Dichlobenil, a cellulose-biosynthesis inhibitor, is a systemic herbicide used for selective weed control of many annual perennial weeds in woody ornamentals, fruit orchards, vineyards, brush fruit, forest plantations, etc.
Trade Name. Sibenil (Siagra).

Ioxynil [*1689-83-4*], 4-hydroxy-3,5-diiodobenzonitrile, $C_7H_3I_2NO$, M_r 370.9, *mp* 212 – 213 °C, is a colorless solid which is moderately soluble in water, fairly soluble in acetone, ethanol, methanol, and chloroform, and readily soluble in cyclohexanone, tetrahydrofuran, and dimethylformamide [23, p. 718].

Ioxynil is produced by iodination of 4-hydroxybenzonitrile with iodine monochloride [128].

Ioxynil is a selective herbicide used post-emergence to control a wide range of annual broad-leaved weeds in cereals, leeks, onions, garlic, on lawns, and on newly sown turf.
Trade Names. Actril, Totril (Rhône-Polenc); Sanoxynil (Sanachem); Trionyl (Agriphar), etc.

7.8.17. Triazinones

Hexazinone [*51235-04-2*], 3-cyclohexyl-6-dimethylamino-1-methyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione, $C_{12}H_{20}N_4O_2$, M_r 252.3, *mp* 115 – 117 °C, forms colorless crystals which are fairly soluble in water and hexane, and are readily soluble in chloroform, methanol, benzene, dimethylformamide, acetone, and toluene [23, p. 677].

Haxazinone is produced by reaction of cyanoamine with methyl chloroformate, followed by methylation, and treatment with dimethylamine and cyclohexyl isocyanate [153].

Hexazinone, which inhibits photosynthesis, is a nonselective herbicide used post-emergence to control many annual and biennial weeds in alfalfa, pineapples, sugar cane, in plantations of certain coniferous species, and on noncrop areas.
Trade Name. Velpar (Du Pont).

Metamitron [*41394-05-2*], 4-amino-4,5-dihydro-3-methyl-6-phenyl-1,2,4-triazin-5-one, $C_{10}H_{10}N_4O$, M_r 202.2, *mp* 166.9°C, is a yellowish crystalline solid which is fairly soluble in water, dichloromethane, methanol, ethanol, chloroform, and toluene [23, p. 799].

Matemitron is produced by reaction of *N′*-acetylbenzylhydrazone with hydroxylamine in pyridine containing potassium hydroxide [154].

Metamitron, a photosynthesis electron-transport inhibitor, is a selective, systemic herbicide used pre-drilling-incorporated and pre- and post-emergence for the control of grasses and broad-leaved weeds in sugar, fodder beets, etc.
Trade Names. Goltix (Bayer); Tornado (Feinchemie Schwebda).

Metribuzin [*21087-64-9*], 4-amino-6-*tert*-butyl-4,5-dihydro-3-methylthio-1,2,4-triazin-5-one, $C_8H_{14}N_4OS$, M_r 214.3 *mp* 126.3 °C, consists of colorless crystals which are moderately

soluble in water and hexane and are readily soluble in dimethylformamide, methanol, and many other organic solvents [23, p. 840].

Metribuzin is produced by reaction of 4-amino-5-oxo-3-thioxo-6-*tert*-butyl-2,3,4,5-tetrahydro-1,2,4-triazine with methyliodide in the presence of methoxide [155].

Metribuzin, a photosynthesis electron-transport inhibitor, is a selective, systemic herbicide used pre- and post-emergence to control many grasses and broad-leaved weeds in soya beans, potatoes, tomatoes, sugar cane, asparagus, maize, and cereals.

Trade Names. Sencor (Bayer); Lexone (Du Pont), etc.

7.8.18. Miscellaneous Herbicides

Bispyribac-sodium [*125401-92-5*], sodium 2,6-bis(4,6-dimethoxypyrimidin-2-yloxy)benzoate, $C_{19}H_{17}N_4NaO_8$, M_r 452.4, *mp* 223 – 224 °C, is a colorless powder which is readily soluble in water and methanol and is sparingly soluble in acetone [23, p. 129].

Bispyribac-sodium is produced by reaction of 2,6-dihydroxybenzoic acid with 2-chloro-4,6-dimethoxypyrimidine [156].

Bispyribac-sodium, which inhibits acetolactate synthase, is a selective, systemic post-emergence herbicide used to control a range of weeds in directly seeded rice.

Trade Names. Nominee, Grass-short (Kumiai); Short-keep (Riken Green).

Butroxydim [*138164-12-2*], 5-(3-butyryl-2,4,6-trimethylphenyl)-2-[1-(ethoxyimino)propyl-3-hydroxycyclohex-2-enone, $C_{24}H_{33}NO_4$, M_r 399.5, *mp* 80.8 °C, is an almost colorless powdery solid which is sparingly soluble in water [23, p. 167].

Butroxydim is produced by reaction of 5-(2,4,6-trimethylphenyl)-2-(1-ethoxyimino)-3-hydroxy-cyclohex-2-enone with butanoic acid chloride in the presence of aluminum trichloride [157].

Butroxydim is a post-emergence grass herbicide used on broad-leaved crops.

Trade Name. Falcon (Zeneca).

Cafenstrole [*125306-83-4*], *N*,*N*-diethyl-3-mesitylsulfonyl-1*H*-1,2,4-triazole-1-carboxamide, $C_{16}H_{22}N_4O_3S$, M_r 350.5, *mp* 114 – 116 °C, forms colorless crystals which are sparingly soluble in water [23, p. 173].

Cafenstrole is produced by reaction of 2-sulfonyl-(2′,4′,6′-trimethylphenyl)-1,3,4-triazole with *N*-diethylcarbamoyl chloride [158].

Cafenstrole is used pre- and early post-emergence for the control of annual weeds in paddy rice.

Cyclosulfamuron [*136849-15-5*], 1-[2-(cyclopropylcarbonyl)phenylsulfamoyl]-3-(4,6-dimethoxypyrimidin-2-yl)urea, $C_{17}H_{19}N_5O_6S$, M_r 421.4, *mp* 160.9 – 162.9 °C, is an almost colorless solid which is practically insoluble in water [23, p. 288].

Cyclosulfamuron is produced by reaction of 2-amino-4,6-dimethoxypyrimidine with isocy-

anate sulfonyl chloride, followed by treatment with *o*-aminophenyl cyclopropyl ketone [159].

Cyclosulfamuron, which inhibits acetohydroxyacid synthase, is used to control a variety of dicotyledonous and sedge weeds in rice, wheat, and barley.
Trade Names. Jin-Qui, Savior (Cyanamid).

Dicamba [*10007-66-5*], 3,6-dichloro-*o*-anisic acid, $C_8H_6Cl_2O_3$, M_r 221.0, *mp* 114 – 116 °C, consists of colorless crystals which are moderately soluble in water and readily soluble in ethanol, cyclohexanone, acetone, dichloromethane, and toluene [23, p. 356].

Dicamba is produced by hydrolysis of 1,2,4-trichlorobenzene with sodium hydroxide, followed by carboxylation, esterification with methanol, methylation of the hydroxyl group, and hydrolysis of the ester to the acid [160].

Dicamba is a selective systemic herbicide, with auxin-like growth-regulator activity, used to control annual and perennial broad-leaved weeds and brush species in cereals, maize, sugar cane, etc., and on turf, pastures, rangeland, and noncropland.
Trade Names. Banvel, Banvel SGF, Marksman (Novartis, BASF), etc.

Diclofop-methyl [*51338-27-3*], (*R*,*S*)-2-[4-(2,4-dichlorophenoxy)phenoxy]propionic acid, $C_{16}H_{14}Cl_2O_4$, M_r 341.2, *mp* 39 – 41 °C, forms colorless crystals which are sparingly soluble in water and are readily soluble in acetone, ethyl acetate, toluene, etc. [23, p. 347].

Diclofop-methyl is produced by reaction of 2,4-dichlorophenol with methyl 4-bromophenoxy-2-propionate [161].

Diclofop-methyl, a fatty-acid-synthesis inhibitor, is a selective, systemic herbicide used post-emergence to control wild oats, wild millet, and other annual grass weeds in many crops.
Trade Names. Hoegrass, Hoelon, Illoxan (AgrEvo).

Dimethenamid [*87674-68-8*], (*R*,*S*)-2-chloro-*N*-(2,4-dimethyl-3-thienyl)-*N*-(2-methoxy-1-methylethyl)acetamide, $C_{12}H_{18}ClNO_2S$, M_r 275.8, *bp* 127 °C/26.7 Pa, is a yellow-brown viscous liquid which is fairly soluble in water and readily soluble in heptane, ethanol, and diethyl ether [23, p. 409].

Dimethenamid is produced by reaction of 2,4-dimethyl-3-aminothiene with 2-chloro-3-methoxypropane, followed by treatment with chloroacetyl chloride [162].

Dimethenamid is used pre-emergence for the control of annual grasses and many broad-leaved weeds in maize, soya beans, and other crops.
Trade Name. Frontier (BASF).

Flupoxam [*119126-15-7*], 1-[4-chloro-3-(2,2,3,3,3-pentafluoropropoxymethyl)phenyl-5-phenyl-1*H*-1,2,4-triazole-3-carboxamide, $C_{19}H_{14}ClF_5N_4O_2$, M_r 460.8, *mp* 144 – 148 °C, forms light beige crystals which are sparingly soluble in water and are readily soluble in methanol, acetone, and ethyl acetate [23, p. 583].

Flupoxam is produced by reduction of the nitro group of 2-chloro-5-nitrobenzene, followed by diazotization, addition of benzylamino ethylcarboxylate, and cyclization of the product [163].

Flupoxam is a cell-elongation inhibitor, used pre- and post-emergence to control annual broad-leaved weeds in winter wheat and winter barley.
Trade Name. Ovation (Synexus).

Fluthiacet-methyl [*117337-16-6*], methyl [2-chloro-4-fluoro-5-(5,6,8-tetrahydro-3-oxo-1*H*,3*H*-[1,3,4,]thiadiazolo[3,4-*a*]pyridazin-1-ylideneamino)phenylthio] acetate, $C_{15}H_{15}ClFN_3O_3S_2$, M_r 403.9, *mp* 105.0 – 106.5 °C, is a colorless powder which is sparingly soluble in water, moderately soluble in methanol and dichloromethane, and dissolves well in acetone, acetonitrile, and ethyl acetate [23, p. 606].

Fluthiacet-methyl is produced by reaction of 1-[(2-fluoro-4-chloro-5-thiomethylacetate)phenylthiocarbamoyl]-2-methoxycarbonylhexahydropyridazine with methanolic potassium hydroxide, followed by treatment with trichloromethyl chloroformate [164].

Fluthiacet-methyl, which inhibits protoporphyrinogen oxidase, is a selective contact herbicide used post-emergence for the control of broad-leaved weeds in maize and soya beans.
Trade Name. Action (Novartis).

Fluthiamide (BAY FOE 5043) [*142459-58-3*], 4′-fluoro-*N*-isopropyl-2-(5-trifluoromethyl-1,3,4-thiadiazol-2-yloxy)acetamide, $C_{14}H_{13}F_4N_3O_2S$, M_r 363.4, *mp* 75 – 77 °C, is a colorless to tan solid which is moderately soluble in water [23, p. 82].

Fluthiamide is produced by reaction of *p*-fluoro-*N*-propylalanine with 5-trifluoromethyl-1,3,4-thiadiazol-2-oxyacetyl chloride [165].

Fluthiamide, which inhibits cell division and growth, is used pre- and early post-emergence. It is under development for the control of a broad spectrum of grass in a wide range of crops.
Trade Name. Axiom (Bayer).

Indanofan [*133220-30-1*], (*R*,*S*)-2-[2-(3-chlorophenyl)-2,3-epoxypropyl]-2-ethylindan-1,3-dione, $C_{20}H_{17}ClO_3$, M_r 340.8, *mp* 60.0 – 62.5 °C, is sparingly soluble in water [23, p. 715].

Indanofan is produced by reaction of 2-[2-(3-chlorophenyl)propen-3-yl]-2-ethyllindan-1,3-dione with peracetic acid [166].

Indanofan is under development by Mitsubishi, for pre-and post-emergence use, for the control of weeds in transplanted rice.

Isoxaflutole [*141112-29-0*], 5-cyclopropyl-1,2-oxazol-4-yl α,α,α-trifluoro-2-mesyl-*p*-tolyl ketone, $C_{15}H_{12}F_3NO_4S$, M_r 359.3, *mp* 140 °C, is a colorless to pale yellow solid which is sparingly soluble in water [23, p. 737].

Isoxaflutole is produced by reaction of 1-(4-trifluoromethyl-2-methylsulfonylphenyl)-3-cyclopropyl-2-ethoxymethylenepropane-1,3-dione with hydroxylamine [167].

Isoxaflutole, which inhibits *p*-hydoxyphenyl pyruvate dioxygenase, is a systemic herbicide used pre-emergence or pre-planting for the control of a broad spectrum of grass and broad-leaved weeds in maize.
Trade Names. Balance, (Rhône-Poulenc).

Mefenacet [*73250-68-7*], 2-(1,3-benzothiazol-2-yloxy)-*N*-methylacetanilide, $C_{16}H_{14}N_2O_2S$, M_r 298.4, *mp* 134.8 °C, consists of colorless crystals which are sparingly soluble in water, moderately soluble in toluene and isopropyl alcohol, and readily soluble in dichloromethane [23, p. 779].

Mefenacet is prepared by reaction of 2-chlorobenzthiazol with *N*-methylbenzene hydroxyacetamide [165].

Mefenacet, a selective herbicide which inhibits cell growth and cell division, is used pre- and post-emergence mainly in transplanted rice.
Trade Names. Act Nihon (Bayer, Nissan, Yashima); Hinochloa, Rancho (Bayer); Zark (Du Pont, Kumiai, Nihon Bayer).

Metosulam [*139528-85-1*], 2′,6′-dichloro-5,7-dimethoxy-3′-methyl[1,2,4]triazolo[1,5-a]pyrimidine-2-sulfonanilide, $C_{14}H_{13}Cl_2N_5O_4S$, M_r 418.3, *mp* 210 – 211.5 °C, is a cream- to tan-colored powder which is moderately soluble in water, hexane and toluene and is fairly soluble in acetone, acetonitrile, and dichloromethane [23, p. 836].

Metosulam is produced by reaction of 4,6-dimethoxy-(2-sulfonyl)-2,3-triazolyl pyrimidine chloride with 2,6-dichloro-5-methylaniline [168].

Metosulam, which inhibits acetolactate synthase, is used pre- and post-emergence for the control of broad-leaved weeds in wheat, barley, rye, and maize.
Trade Names. Pronto, Sansac, Sinal (DowElanco).

Propaquizafop [*111479-05-1*], 2-isopropyl-ideneamino-oxyethyl (*R*)-2[4-(6-chloroquinoxalin-2-yloxy)phenoxy]propionate, $C_{22}H_{22}ClN_3O_5$, M_r 443.9, *mp* 66.3 °C, forms colorless crystals which are sparingly soluble in water, readily soluble in acetone and toluene, and fairly soluble in *n*-hexane and ethanol [23, p. 1021].

Propaquizafop is produced by reaction of 2-(6-chloroaminoxalinyl)phenoxypropionic acid ethoxycarbonyl chloride with isopropylidene hydroxylamine [169].

Propaquizafop, which inhibits fatty acid synthesis, is a systemic, post-emergence herbicide used for the control of a wide range of annual and perennial grasses in soya beans, sugar cane, cotton, vegetables, etc.
Trade Name. Agil (Novartis).

Pyridate [*55512-33-9*], 6-chloro-3-phenylpyridazin-4-yl *S*-octyl thiocarbonate, $C_{19}H_{23}ClN_2O_2S$, M_r 378.9, *mp* 27 °C, forms colorless crystals which are sparingly soluble in water and are readily soluble in many organic solvents [23, p. 1064].

Pyridate is produced by reaction of acetophenone with diethyloxalate, followed by reaction with hydrazine, phosphorus pentachloride, and octylmercaptocarboxy chloride [170].

Pyridate, which inhibits photosystem II electron transport in photosynthesis, is a selective herbicide used post-emergence to control annual broad-leaved weeds in maize, sweetcorn, cereals, rice, and other crops.
Trade Names. Lentagran (Novartis); Pirate (Barclay).

Pyrithiobac-sodium [*123343-16-8*], sodium 2-chloro-6-(4,6-dimethoxypyrimidin-2-ylthio) benzoate, $C_{13}H_{10}ClN_2NaO_4S$, M_r 348.7, *mp* 233.8 – 234.2 °C, is a colorless solid which is readily soluble in water, acetone, and methanol and is fairly soluble in dichloromethane [23, p. 1073].

Pyrithiobac-sodium is produced by diazotization of 2-amino-6-chlorobenzoic acid ethyl ester, followed by treatment with 4,6-dimeth-

oxy-2-mercaptopyrimidine, and hydrolysis of the ester to the acid [171].

Pyrithiobac-sodium, which inhibits acetolactate synthase, is a selective herbicide used pre- and post-emergence for the control of a wide range of broad-leaved weeds in cotton.
Trade Name. Staple (Du Pont, Kumiai).

7.9. Toxicology

7.9.1. Diphenyl Ethers

Acifluorfen Na salt: [*62476-59-9*], [23, p. 12]

LC_{50} (rat, 4-h inhalation)	> 5.6	mg/L air	
Rabbit: nonirritating to skin and eyes			
Guinea pig: not a skin sensitizer			
Nonmutagenic (*in vitro*, various assays) [177]			
NOEL/NOAEL			
Reproduction.			
Rat (2-generation feed)	36.9	$mg\,kg^{-1}\,d^{-1}$ (parental)	[177]

Teratogenicity.

Rat (gavage)	200	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[177]
	> 2400	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[177]
Rabbit (gavage)	15	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[177]
	> 120	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[177]

Chronic.

Rat (2-year feed)	ca. 20	$mg\,kg^{-1}\,d^{-1}$	[177]
Dog (1-year feed)	ca. 65 – 92	$mg\,kg^{-1}\,d^{-1}$	[177]
Mouse (2-year feed)	ca. 60 – 404	$mg\,kg^{-1}\,d^{-1}$	[177]

Ethametsulfuron-methyl [*97780-06-8*], [23, p. 475]

LD_{50} (rat, oral)	> 5000	mg/kg
LD_{50} (rabbit, oral)	> 5000	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 5.7	mg/L air

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic [174, p. 123]
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	ca. 300	$mg\,kg^{-1}\,d^{-1}$ (parental)	[174, p. 123]

Teratogenicity.

Rat (gavage)	1000	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[174, p. 123]
Rabbit (gavage)	250	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[174, p. 123]

Chronic.

Rat (1-year feed)	ca. 25	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	ca. 80	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	ca. 710	$mg\,kg^{-1}\,d^{-1}$

Ethoxysulfuron [*126801-58-9*], [23, p. 488]

LD_{50} (rat, oral)	> 3270	mg/kg
LD_{50} (rat, dermal)	> 4000	mg/kg

Rabbit: nonirritating to skin and eyes
Nonmutagenic (Ames test)

Flazasulfuron [*104040-78-0*], [23, p. 550]

LD_{50} (rat, oral)	> 5000	mg/kg
LD_{50} (mouse, oral)	> 5000	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	5.99	mg/L air

Rabbit: nonirritating to skin
Rabbit: moderately irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic

Chronic.

Rat (2-year feed)	ca. 1.3	$mg\,kg^{-1}\,d^{-1}$

Flupyrsulfuron-methyl-sodium [*144740-54-5*], [23, p. 586]

LD_{50} (rat, oral)	> 5000	mg/kg
LD_{50} (mouse, oral)	> 5000	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 2.0	mg/L air

Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic (Ames test)
NOEL/NOAEL

Chronic.

Rat (2-year feed)	ca. 17.5	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	13.6	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.035\,mg\,kg^{-1}\,d^{-1}$

Halosulfuron-methyl [*100784-20-1*], [23, p. 657]

LD_{50} (rat, oral)	8865	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 6.0	mg/L air

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: not a skin sensitizer
NOEL/NOAEL

Chronic.

Rat (2-year feed)	ca. 50	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	1.0	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	ca. 430	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.1\,mg\,kg^{-1}\,d^{-1}$

Imazosulfuron [*122548-33-8*], [23, p. 703]

LD_{50} (rat, oral)	> 5000	mg/kg
LD_{50} (mouse, oral)	> 5000	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 2.4	mg/L air

Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic [178]
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	77.8	$mg\,kg^{-1}\,d^{-1}$ (parental)	[178]

Teratogenicity.

Rat (gavage)	1000	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[178]
	1500	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[178]
Rabbit (gavage)	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[178]
	125	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[178]

Chronic.

Rat (2-year feed)	106	$mg\,kg^{-1}\,d^{-1}$	[23] [178]

Dog (1-year feed)	75	$mg\,kg^{-1}\,d^{-1}$	[23] [178]
Mouse (18-month feed)	72.7	$mg\,kg^{-1}\,d^{-1}$	[178]

ADI: $0.7\,mg\,kg^{-1}\,d^{-1}$

Metsulfuron-methyl [*74223-64-6*], [23, p. 842]

LD_{50} (rat, oral)	> 5000	mg/kg	
LD_{50} (rabbit, dermal)	> 2000	mg/kg	
LC_{50} (rat, 4-h inhalation)	> 5.3	mg/L air	[174, p. 203]

Rabbit: moderately irritating to eyes
Guinea pig: mildly irritating to skin
Guinea pig: not a skin sensitizer
Nonmutagenic (test battery)
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	ca. 30	$mg\,kg^{-1}\,d^{-1}$	[174, p. 203]

Teratogenicity.

Rat (gavage)	40	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[174, p. 203]
Rabbit (gavage)	25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[174, p. 203]

Chronic.

Rat (2-year feed)	ca. 25	$mg\,kg^{-1}\,d^{-1}$	
Dog (1-year feed)	ca. 13	$mg\,kg^{-1}\,d^{-1}$	
Mouse (18-month feed)	ca. 710	$mg\,kg^{-1}\,d^{-1}$	[174, p. 203]

ADI: $0.0125\,mg\,kg^{-1}\,d^{-1}$

Nicosulfuron [*111991-09-4*], [23, p. 877]

LD_{50} (rat, oral)	> 5000	mg/kg	
LD_{50} (mouse, oral)	> 5000	mg/kg	
LD_{50} (rat, dermal)	> 2000	mg/kg	
LC_{50} (rat, 4-h inhalation)	5.9	mg/L air	[174, p. 216]

Rabbit: nonirritating to skin
Rabbit: moderately irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic (test battery) [179]
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	287	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[179]

Teratogenicity.

Rat (feed)	300	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[179]
Rabbit (feed)	100	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[179]
	500	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[179]

Chronic.

Rat (2-year feed)	> 786	$mg\,kg^{-1}\,d^{-1}$	[179]
Dog (1-year feed)	125	$mg\,kg^{-1}\,d^{-1}$	[179]
Mouse (18-month feed)	> 993	$mg\,kg^{-1}\,d^{-1}$	[179]

ADI/RfD: $1.25\,mg\,kg^{-1}\,d^{-1}$ [179]

Oxasulfuron [*144651-06-9*], [23, p. 911]

LD_{50} (rat, oral)	> 5000	mg/kg

	75	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[174, p. 37]
Rabbit (gavage)	100	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[174, p. 37]
Chronic.			
Rat (2-year feed)	ca. 2.5	$mg\,kg^{-1}\,d^{-1}$	[174, p. 37]
Dog (1-year feed)	ca. 17	$mg\,kg^{-1}\,d^{-1}$	[174, p. 37]
Mouse (18-month feed)	12.5	$mg\,kg^{-1}\,d^{-1}$	

ADI: $0.13\,mg\,kg^{-1}\,d^{-1}$ [23, p. 140]

Lenacil [*2164-08-1*], [23, p. 748]

LD_{50} (rat, oral)	> 11 000	mg/kg
LD_{50} (rabbit, dermal)	> 5000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 5.2	mg/L air

Rabbit: slightly irritating to skin

Terbacil [*5902-51-2*], [197]

LD_{50} (rat, oral)	934 – 1255	mg/kg	
LD_{50} (rabbit, dermal)	> 5000	mg/kg	
LC_{50} (rat, 4-h inhalation)	> 4.4	mg/L air	[174, p. 278]

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: not a skin sensitizer [174, p. 278]
Nonmutagenic (multiple assays) [174, p. 278]
NOEL/NOAEL

Reproduction.			
Rat (3-generation feed)	30	$mg\,kg^{-1}\,d^{-1}$	[174, p. 278]
Teratogenicity.			
Rat (gavage)	62.5	$mg\,kg^{-1}\,d^{-1}$ (maternal)	
Rabbit (gavage)	200	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	
Chronic.			
Rat (2-year feed)	ca. 12.5	$mg\,kg^{-1}\,d^{-1}$	
Dog (2-year feed)	ca. 1.25	$mg\,kg^{-1}\,d^{-1}$	
Mouse (2-year feed)	7	$mg\,kg^{-1}\,d^{-1}$	[174, p. 278]

ADI: $0.0125\,mg\,kg^{-1}\,d^{-1}$

7.9.11. Pyridines

Clopyralid [*1702-17-6*], [174, p. 66]

LD_{50} (rat, oral)	4300	mg/kg	
LD_{50} (mouse, oral)	> 5000	mg/kg	
LD_{50} (rabbit, dermal)	> 2000	mg/kg	
LC_{50} (rat, 4-h inhalation)	1.3	mg/L air	

Rabbit: slightly irritating to skin
Rabbit: severely irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic (multiple assays)
NOEL/NOAEL

Reproduction.			
Rat (2-generation feed)	500	$mg\,kg^{-1}\,d^{-1}$	
Teratogenicity.			
Rat (gavage)	> 250	$mg\,kg^{-1}\,d^{-1}$	
Rabbit (gavage)	110	$mg\,kg^{-1}\,d^{-1}$	
Chronic.			
Rat (2-year feed)	15	$mg\,kg^{-1}\,d^{-1}$	
Dog (1-year feed)	100	$mg\,kg^{-1}\,d^{-1}$	
Mouse (18-month feed)	500	$mg\,kg^{-1}\,d^{-1}$	[23]

ADI: $0.15\,mg\,kg^{-1}\,d^{-1}$ [23, p. 260]

Dilufenican [*83164-33-4*], [23, p. 397]

LD_{50} (rat, oral)	> 2000	mg/kg
LD_{50} (mouse, oral)	> 1000	mg/kg
LD_{50} (rabbit, oral)	> 5000	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 2.34	mg/L air

Rabbit: nonirritating to skin and eyes
Nonmutagenic (Ames test)
NOEL/NOAEL

Subchronic.		
Rat (90-day feed)	ca. 33	$mg\,kg^{-1}\,d^{-1}$
Dog (90-day feed)	ca. 30	$mg\,kg^{-1}\,d^{-1}$

Diflufenzopyr (BAS 654 00 H) [*109293-97-2*], [23, p. 81]

LD_{50} (rat, oral)	> 5000	mg/kg
LD_{50} (rabbit, dermal)	> 5000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 3.14	mg/L air

Dithiopyr [*97886-45-8*], [198]

LD_{50} (rat, oral)	> 5000	mg/kg	[174, p. 111]
LD_{50} (mouse, oral)	> 5000	mg/kg	[23, p. 442]
LD_{50} (rat, dermal)	> 5000	mg/kg	[23, p. 442]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[174, p. 111]
LC_{50} (rat, 4-h inhalation)	> 6	mg/L air	[174, p. 111]

Rabbit: nonirritating to skin [174, p. 111]
Rabbit: slightly irritating to eyes [174, p. 111]
Guinea pig: not a skin sensitizer [174, p. 111]
Nonmutagenic
NOEL/NOAEL
Reproduction.

Rat (2-generation feed)	ca. 1.5	$mg\,kg^{-1}\,d^{-1}$ (parental)
	ca. 150	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Teratogenicity.

Rat (gavage)	300	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	1000	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	500	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	1000	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Chronic.

Rat (2-year feed)	0.36	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	ca. 0.5	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	ca. 0.31	$mg\,kg^{-1}\,d^{-1}$

Picloram [*1918-02-1*], [174, p. 235]

LD_{50} (rat, oral)	4012 to > 5000	mg/kg
LD_{50} (mouse, oral)	2000 – 4000	mg/kg
LD_{50} (rabbit, oral)	ca. 2000	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 0.035	mg/L air

Rabbit: nonirritating to skin
Rabbit: moderately irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL
Reproduction.

Rat (2-generation feed)	200	$mg\,kg^{-1}\,d^{-1}$ (parental)
	1000	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Teratogenicity.

Rat (gavage)	> 400	$mg\,kg^{-1}\,d^{-1}$
Rabbit (gavage)	> 400	$mg\,kg^{-1}\,d^{-1}$

Chronic.

Rat (2-year feed)	20	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	> 175	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	1000	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.2 $mg\,kg^{-1}\,d^{-1}$ [23, p. 977]

Thiazopyr [*117718-60-2*], [174, p. 280]

LD_{50} (rat, oral)	> 5000	mg/kg	
LD_{50} (rabbit, dermal)	> 5000	mg/kg	
LC_{50} (rat, 4-h inhalation)	> 1.2	mg/L air	

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL
Chronic.

Rat (2-year feed)	0.36	$mg\,kg^{-1}\,d^{-1}$ (parental)	[23, p. 1185]
Dog (1-year feed)	0.5	$mg\,kg^{-1}\,d^{-1}$	[23, p. 1185]

7.9.12. Hydroxybenzoniriles

Bromofenoxim [*13181-17-4*], [23, p. 145]

LD_{50} (rat, oral)	1217	mg/kg
LD_{50} (mouse, oral)	940	mg/kg
LD_{50} (dog, oral)	> 1000	mg/kg
LD_{50} (rat, dermal)	> 3000	mg/kg
LC_{50} (rat, 6-h inhalation)	> 0.242	mg/L air

Rabbit: mildly irritating to skin and eyes
NOEL/NOAEL
Subchronic.

Dog (90-day feed)	3	$mg\,kg^{-1}\,d^{-1}$

Chronic.

Rat (2-year feed)	3.8	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.0013 $mg\,kg^{-1}\,d^{-1}$

Bromoxynil [*1689-84-5*], [174, p. 39]

LD_{50} (rat, oral)	440	mg/kg	
LD_{50} (mouse, oral)	160	mg/kg	
LD_{50} (rabbit, oral)	335	mg/kg	
LD_{50} (rdog, oral)	ca. 100	mg/kg	[23, p. 149]
LD_{50} (rat, dermal)	> 3660	mg/kg	
LD_{50} (rabbit, dermal)	3660	mg/kg	[23, p. 149]
LC_{50} (rat, 4-h inhalation)	0.41	mg/L air	[23, p. 149]

Rabbit: mildly irritating to skin and eyes
Guinea pig: not a skin sensitizer [23, p. 149]
NOEL/NOAEL

Chronic.

Rat (2-year feed)	ca. 5	$mg\,kg^{-1}\,d^{-1}$	[23, p. 149]

7.9.13. [Thio] Carbamates

Asulam [*3337-71-1*], [174, p. 18]

LD_{50} (rat, oral)	> 5000	mg/kg	
LD_{50} (mouse, oral)	> 4000	mg/kg	[23, p. 53]
LD_{50} (rabbit, oral)	> 4000	mg/kg	[23, p. 53]
LD_{50} (dog, oral)	> 4000	mg/kg	[23, p. 53]
LD_{50} (rat, dermal)	> 2000	mg/kg	
LD_{50} (rabbit, dermal)	> 2000	mg/kg	
LC_{50} (rat, 6-h inhalation)	> 1.8	mg/L air	

Rabbit: slightly irritating to skin
Rabbit: irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	1250	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Teratogenicity.

Rat (gavage)	> 2000	$mg\,kg^{-1}\,d^{-1}$
Rabbit (gavage)	750	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	1500	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Chronic.

Rat (2-year feed)	50	$mg\,kg^{-1}\,d^{-1}$
Dog (6-month feed)	60	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	713	$mg\,kg^{-1}\,d^{-1}$

Butylate [*2008-41-5*], [174, p. 43]

LD_{50} (rat, oral)	4660 – 5430	mg/kg	
LD_{50} (guinea pig, oral)	1660	mg/kg	
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[23, p. 170]
LC_{50} (rat, 4-h inhalation)	4.64	mg/L air	

Rabbit: mildly irritating to skin
Rabbit: nonirritating to eyes
Guinea pig: a potential skin sensitizer
Nonmutagenic (Ames test)
NOEL/NOAEL

Subchronic.

Rat (90-day feed)	32	$mg\,kg^{-1}\,d^{-1}$
Dog (90-day feed)	40	$mg\,kg^{-1}\,d^{-1}$

Chronic.

Rat (2-year feed)	50	$mg\,kg^{-1}\,d^{-1}$

Carbetamide [*16118-49-3*], [23, p. 184]

LD_{50} (rat, oral)	> 2000	mg/kg
LD_{50} (mouse, oral)	1720	mg/kg
LD_{50} (dog, oral)	900	mg/kg
LD_{50} (rabbit, dermal)	> 500	mg/kg
LC_{50} (rat, 4-h inhalation)	> 0.13	mg/L air

Rabbit: nonirritating to skin
NOEL/NOAEL

Subchronic.

Rat (90-day feed)	ca. 210	$mg\,kg^{-1}\,d^{-1}$
Dog (90-day feed)	ca. 350	$mg\,kg^{-1}\,d^{-1}$

Chlorpropham [*101-21-3*], [23, p. 233]

LD_{50} (rat, oral)	5000 – 7500	mg/kg
LD_{50} (rabbit, oral)	5000	mg/kg

NOEL/NOAEL

Chronic.

Rat (2-year feed)	ca. 100	$mg\,kg^{-1}\,d^{-1}$
Dog (2-year feed)	ca. 50	$mg\,kg^{-1}\,d^{-1}$

Cycloate [*1134-23-2*], [174, p. 75]

LD_{50} (rat, oral)	2275 – 3200	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	0.0047	mg/L air

Rabbit: mildly irritating to skin and eyes
Guinea pig: a potential skin sensitizer
NOEL/NOAEL

Subchronic.

Rat (90-day feed)	55	$mg\,kg^{-1}\,d^{-1}$
Dog (90-day feed)	240	$mg\,kg^{-1}\,d^{-1}$

Desmedipham [*13684-56-5*], [174, p. 87]

LD_{50} (rat, oral)	> 10 250	mg/kg

Rat (2-year feed) 0.5 mg kg^{-1} d^{-1}
Mouse (18-month feed) > 65 mg kg^{-1} d^{-1}

Pyributicarb [*88678-67-5*], [23, p. 1060]

LD_{50} (rat, oral) > 5000 mg/kg
LD_{50} (mouse, oral) > 5000 mg/kg
LD_{50} (rat, dermal) > 5000 mg/kg
LC_{50} (rat, 4-h inhalation) > 6.52 mg/L air
Rabbit: slightly irritating to skin
Rabbit: nonirritating to eyes
Guinea pig: not a skin sensitizer
NOEL/NOAEL
Chronic.
Rat (2-year feed) 0.75 mg kg^{-1} d^{-1}

Thiobencarb [*28249-77-6*], [174, p. 284]

LD_{50} (rat, oral) 1033 – 1130 mg/kg
LD_{50} (mouse, oral) 2745 mg/kg
LD_{50} (rat, dermal) > 2000 mg/kg
LD_{50} (rabbit, dermal) > 2000 mg/kg [23, p. 1192]
LC_{50} (rat, 1-h inhalation) > 3 mg/L air
Rabbit: mildly irritating to skin
Rabbit: moderately irritating to eyes
Nonmutagenic [23, p. 1192]
NOEL/NOAEL
Reproduction.
Rat (2-generation feed) < 2 mg kg^{-1} d^{-1}
Teratogenicity.
Rat (gavage) 25 mg kg^{-1} d^{-1}
Rabbit (gavage) 100 mg kg^{-1} d^{-1}
Chronic.
Rat (2-year feed) 0.9 – 1.0 mg kg^{-1} d^{-1}
Dog (1-year feed) 1.0 mg kg^{-1} d^{-1}
Mouse (18-month feed) 25 mg kg^{-1} d^{-1}
ADI: 0.009 mg kg^{-1} d^{-1} [23, p. 1192]

Triallate [*2303-17-5*], [174, p. 285]

LD_{50} (rat, oral) 1100 mg/kg
LD_{50} (rabbit, dermal) 8200 mg/kg
LC_{50} (rat, 12-h inhalation) > 5.3 mg/L air
Rabbit: slightly [23] to moderately irritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic (*in vivo*, but positive responses *in vitro*)
NOEL/NOAEL
Reproduction.
Rat (2-generation feed) 7.5 mg kg^{-1} d^{-1} (developmental)
Teratogenicity.
Rat (gavage) 30 mg kg^{-1} d^{-1} (developmental)
Rabbit (gavage) 15 mg kg^{-1} d^{-1} (developmental)
Chronic.
Rat (2-year feed) 2.5 mg kg^{-1} d^{-1}
Dog (1-year feed) 2.5 mg kg^{-1} d^{-1}
Mouse (2-year feed) 4 mg kg^{-1} d^{-1}
Hamster (22-month feed) 18 mg kg^{-1} d^{-1}
ADI: 0.025 mg kg^{-1} d^{-1} [23, p. 1200]

Vernolate [*1929-77-7*], [174, p. 202]

LD_{50} (rat, oral) 1200 – 1900 mg/kg
LD_{50} (rabbit, dermal) 4640 mg/kg
LC_{50} (rat, 4-h inhalation) > 5 mg/L air [23, p. 1264]
Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Mutagenicity: Essentially non-genotoxic
NOEL/NOAEL
Reproduction.
Rat (2-generation feed) 1 mg kg^{-1} d^{-1} (maternal and developmental) [199]
25 mg kg^{-1} d^{-1} [199]
Teratogenicity.
Rabbit (gavage) > 200 mg kg^{-1} d^{-1} (maternal and developmental) [199]
Subchronic.
Dog (90-day feed) 38 mg kg^{-1} d^{-1}
Chronic.
Rat (51-week feed) 5 mg kg^{-1} d^{-1} [23, p. 1264]
Mouse (2-year feed) 100 mg kg^{-1} d^{-1} [23, p. 1264]

7.9.14. Organophosphorous Compounds

Anilofos [*64249-01-0*], [23, p. 47]

LD_{50} (rat, oral)	472 – 830	mg/kg	
LD_{50} (rat, dermal)	> 2000	mg/kg	
LC_{50} (rat, 4-h inhalation)	26	mg/L air	

Rabbit: slightly irritating to skin and eyes

Bensulide [*741-58-2*], [23, p. 106]

LD_{50} (rat, oral)	270 – 360	mg/kg	
LD_{50} (rat, dermal)	> 2000	mg/kg	
LD_{50} (rabbit, dermal)	3950	mg/kg	[174, p. 31]
LC_{50} (rat, 4-h inhalation)	> 1.75	mg/L air	

Rabbit: mildly irritating to skin and eyes
Guinea pig: not a skin sensitizer
NOEL/NOAEL
Subchronic.

Rat (90-day feed)	25	$mg\,kg^{-1}\,d^{-1}$	[174, p. 31]
Dog (90-day feed)	2.5	$mg\,kg^{-1}\,d^{-1}$	[174, p. 31]
Mouse (90-day feed)	30	$mg\,kg^{-1}\,d^{-1}$	

Bilanafos [*35597-43-4*], [23, p. 120]

LD_{50} (rat, oral)	268 – 404	mg/kg
LD_{50} (rat, dermal)	> 5000	mg/kg

Rabbit: nonirritating to skin and eyes
Nonmutagenic (Ames test)

Butamifos [*36335-67-8*], [23, p. 161]

LD_{50} (rat, oral)	845 – 1070	mg/kg
LD_{50} (rat, dermal)	> 5000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 1.2	mg/L air

Rabbit: nonirritating to skin and eyes

Glufosinate-ammonium [*77182-82-2*], [200]

LD_{50} (rat, oral)	1510 – 2000	mg/kg
LD_{50} (mouse, oral)	416 – 464	mg/kg
LD_{50} (dog, oral)	> 200 – 400	mg/kg
LD_{50} (rat, i.p.)	83 – 204	mg/kg
LD_{50} (rat, dermal)	ca. 4000	mg/kg
LD_{50} (rabbit, dermal)	ca. 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 0.621	mg/L air (aerosol)
	1.26 – 2.6	mg/L air (dust)

Rabbit: nonirritating to skin and eyes [23, p. 643], slightly irritating to skin [174, p. 147]
Nonmutagenic
Not neurotoxic (hens)
Reproduction.

Rat (2-generation feed)	6	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)

Teratogenicity.

Rat (gavage)	2.2	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	2	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	6.3	$mg\,kg^{-1}\,d^{-1}$ (developmental)

NOEL/NOAEL
Chronic.

Rat (2-year feed)	2	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	4.5	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	11	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$

Glyphosate [*1071-83-6*], [201]

LD_{50} (rat, oral)	5600	mg/kg	[174, p. 149]
LD_{50} (mouse, oral)	11 300	mg/kg	[23, p. 646]
LD_{50} (rat, dermal)	> 5010	mg/kg	[23, p. 646]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[174, p. 149]
LD_{50} (mouse, dermal)	7030	mg/kg	[23, p. 646]

Rabbit: nonirritating to skin [174, p. 149]
Rabbit: slightly irritating to eyes [174, p. 149]
Guinea pig: not a skin sensitizer
Nonmutagenic
Non-neurotoxic (multiple assays) [174, p. 149]
NOEL/NOAEL
Reproduction.

Rat (2-generation feed)	30	$mg\,kg^{-1}\,d^{-1}$

Teratogenicity.

Rat (gavage)	1000	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	175	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	350	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Chronic.

Rat (26-month feed)	> 31	$mg\,kg^{-1}\,d^{-1}$	
Rat (2-year feed)	400	$mg\,kg^{-1}\,d^{-1}$	[174, p. 149]
Dog (1-year capsules)	500	$mg\,kg^{-1}\,d^{-1}$	
Mouse (2-year feed)	814	$mg\,kg^{-1}\,d^{-1}$	

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$

Piperophos [*24151-93-7*], [202]

LD_{50} (rat, oral)	315 – 335	mg/kg	
LD_{50} (mouse, oral)	330 – 410	mg/kg	
LD_{50} (rat, i.p.)	94 – 140	mg/kg	
LD_{50} (mouse, i.p.)	250 – 290	mg/kg	
LD_{50} (rat, dermal)	> 2150	mg/kg	[23]
	> 4000	mg/kg	
LC_{50} (rat, 1-h inhalation)	> 1.96	mg/L air	

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Guinea pig: a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.		
Rat (2-generation feed)	6.7	$mg\,kg^{-1}\,d^{-1}$ (parental)
	> 65	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Teratogenicity.		
Rat (gavage)	20	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 20	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	1	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 16	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	0.37	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	0.036	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	27.6	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.001 $mg\,kg^{-1}\,d^{-1}$

7.9.15. Cyclohexanedione Oximes

Alloxydim-sodium [*66003-55-2*], [23, p. 30]

LD_{50} (rat, oral)	2260 – 2322	mg/kg
LD_{50} (mouse, oral)	3000 – 4600	mg/kg
LD_{50} (rat, dermal)	> 5000	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 4.3	mg/L air

NOEL/NOAEL

Chronic.		
Rat (2-year feed)	ca. 5	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	ca. 14	$mg\,kg^{-1}\,d^{-1}$

Clethodim [*99129-21-2*], [203]

LD_{50} (rat, oral)	1360 – 1630	mg/kg	[23, p. 250]
LD_{50} (mouse, oral)	2430 – 2570	mg/kg	
LD_{50} (rabbit, oral)	> 2000, but < 5000	mg/kg	
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[23, p. 250]
LC_{50} (rat, 4-h inhalation)	> 3.9	mg/L air	

Rabbit: slightly irritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.		
Rat (2-generation feed)	39	$mg\,kg^{-1}\,d^{-1}$ (parental)
	> 190	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Teratogenicity.		
Rat (gavage)	100	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	25	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 300	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	16	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year capsule)	1	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	30	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$

Cycloxydim [*101205-02-1*], [204]

LD_{50} (rat, oral)	3830 – 5000	mg/kg
LD_{50} (mouse, oral)	> 5000	mg/kg
LD_{50} (rat, i.p.)	1940 – 2370	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 5.28	mg/L air

Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.		
Rat (multigeneration, drinking water)	10	$mg\,kg^{-1}\,d^{-1}$ (parental)
	38	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Teratogenicity.		
Rat (gavage)	200	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	100	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	200	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year water)	7	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	20	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year water)	> 32	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.07 $mg\,kg^{-1}\,d^{-1}$

Sethoxydim [*74051-80-2*], [205]

LD_{50} (rat, oral)	2676 – 3500	mg/kg	
LD_{50} (mouse, oral)	5600 – 6300	mg/kg	[23, p. 1101]
LD_{50} (rat, dermal)	> 5000	mg/kg	[23, p. 1101]
LD_{50} (mouse, dermal)	> 5000	mg/kg	[23, p. 1101]
LC_{50} (rat, 4-h inhalation)	> 6.28	mg/L air	[23, p. 1101]

Rabbit: nonirritating to skin and eyes [23, p. 1101]
Guinea pig: not a skin sensitizer [23, p. 1101]
Nonmutagenic
NOEL/NOAEL

Teratogenicity.

Rat (gavage)	> 250	mg kg^{-1} d^{-1} (developmental)	
Rabbit (gavage)	160	mg kg^{-1} d^{-1} (maternal and developmental)	
Chronic.			
Rat (2-year feed)	17.2	mg kg^{-1} d^{-1}	[23, p. 1101]
Dog (1-year feed)	8.9	mg kg^{-1} d^{-1}	
Mouse (2-year feed)	18	mg kg^{-1} d^{-1}	

ADI: 0.09 mg kg^{-1} d^{-1}

Tepraloxydim (proposed name: BAS 620H) [*149979-41-9*], [23, p. 80]

No toxicological data available

Tralkoxydim [*87820-88-0*], [23, p. 1211]

LD_{50} (rat, oral)	934 – 1324	mg/kg
LD_{50} (mouse, oral)	1100 – 1231	mg/kg
LD_{50} (rabbit, oral)	> 519	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 3.5	mg/L air

Rabbit: mildly irritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Subchronic.

Rat (90-day feed)	ca. 0.8	mg kg^{-1} d^{-1}
Dog (90-day feed)	ca. 0.125	mg kg^{-1} d^{-1}

7.9.16. Benzonitriles

Dichlobenil [*1194-65-6*], [174, p. 94]

LD_{50} (rat, oral)	4460	mg/kg	
LD_{50} (mouse, oral)	1014 – 1621	mg/kg	
LD_{50} (rat, i.p.)	442	mg/kg	[23, p. 359]
LD_{50} (rat, dermal)	> 1000	mg/kg	
LD_{50} (rabbit, dermal)	> 2000	mg/kg	
LC_{50} (rat, 4-h inhalation)	> 0.25	mg/L air	

Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	ca. 3	mg kg^{-1} d^{-1} (parental)

Teratogenicity.

Rat (gavage)	180	mg kg^{-1} d^{-1}
Rabbit (gavage)	45	mg kg^{-1} d^{-1} (maternal and developmental)
Mouse (gavage)	60	mg kg^{-1} d^{-1}

Chronic.

Rat (2-year feed)	ca. 2.5	mg kg^{-1} d^{-1}
Dog (1-year feed)	ca. 1.25	mg kg^{-1} d^{-1}
Hamster (20-month feed)	ca. 10	mg kg^{-1} d^{-1}

ADI: 0.025 mg kg^{-1} d^{-1} [23, p. 359]

Ioxynil [*1689-83-4*], [174, p. 168]

LD_{50} (rat, oral)	110	mg/kg	
LD_{50} (mouse, oral)	230	mg/kg	[23, p. 718]
LD_{50} (rat, dermal)	> 2000	mg/kg	[23, p. 718]
LD_{50} (rabbit, dermal)	1050	mg/kg	
LC_{50} (rat, 6-h inhalation)	0.4	mg/L air (4-h LC_{50})	

Rabbit: mildly irritating to skin
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL

Reproduction.

Rat (2-generation feed)	> 10	mg kg^{-1} d^{-1}

Teratogenicity.

Rat (gavage)	5	mg kg^{-1} d^{-1}
Rabbit (gavage)	15	mg kg^{-1} d^{-1}

Chronic.

Rat (2-year feed)	0.5	mg kg^{-1} d^{-1}
Dog (30-week feed)	1	mg kg^{-1} d^{-1}
Mouse (18-month feed)	< 1.5	mg kg^{-1} d^{-1}

7.9.17. Triazinones

Hexazinone [*51235-04-2*], [206]

LD_{50} (rat, oral)	1690	mg/kg	[23, p. 677]
LD_{50} (guinea pig, oral)	860	mg/kg	[23, p. 677]
LD_{50} (dog, oral)	> 3400	mg/kg	
LC_{50} (rat, 1-h inhalation)	> 7.48	mg/L air	[23, p. 677]

Guinea pig: nonirritating to skin [23, p. 677]
Rabbit: corrosive
Guinea pig: not a skin sensitizer [174, p. 156]
Nonmutagenic (*in vivo*) [174, p. 156]
NOEL/NOAEL

Reproduction.

Rat (3-generation feed)	ca. 10	mg kg^{-1} d^{-1}	[174, p. 156]

Teratogenicity.

Rat (gavage)	100	mg kg^{-1} d^{-1} (maternal and developmental)
Rabbit (gavage)	50	mg kg^{-1} d^{-1} (maternal and developmental)

Chronic.

Rat (2-year feed)	ca. 10	$mg\,kg^{-1}\,d^{-1}$	
Dog (1-year feed)	ca. 5	$mg\,kg^{-1}\,d^{-1}$	[174, p. 156]
Mouse (2-year feed)	ca. 30	$mg\,kg^{-1}\,d^{-1}$	

Metamitron [*41394-05-2*], [23, p. 799]

LD_{50} (rat, oral)	ca. 1200	mg/kg
LD_{50} (mouse, oral)	ca. 650	mg/kg
LD_{50} (dog, oral)	>1000	mg/kg
LD_{50} (rat, dermal)	>4000	mg/kg
LC_{50} (rat, 4-h inhalation)	>0.33	mg/L air

Rabbit: nonirritating to skin and eyes
NOEL/NOAEL
Chronic.

Rat (2-year feed)	ca. 12.5	$mg\,kg^{-1}\,d^{-1}$
Dog (2-year feed)	ca. 2.5	$mg\,kg^{-1}\,d^{-1}$
Mouse (87-week feed)	ca. 8	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.025\,mg\,kg^{-1}\,d^{-1}$

Metribuzin [*21087-64-9*], [174, p. 200]

LD_{50} (rat, oral)	1090 – 1206	mg/kg	
LD_{50} (mouse, oral)	ca. 700	mg/kg	[23, p. 840]
LD_{50} (guinea pig, oral)	245 – 274	mg/kg	[23, p. 840]
LD_{50} (rabbit, dermal)	$>20\,000$	mg/kg	
LC_{50} (rat, 4-h inhalation)	>0.65	mg/L air	[23, p. 840]

Rabbit: nonrritating to skin and eyes [23, p. 840]
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL
Reproduction.

Rat (3-generation feed)	ca. 2	$mg\,kg^{-1}\,d^{-1}$ (parental)	
	20	$mg\,kg^{-1}\,d^{-1}$ (developmental)	

Teratogenicity.

Rat (gavage)	ca. <25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	
	25	$mg\,kg^{-1}\,d^{-1}$ (developmental)	
Rabbit (gavage)	15	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	
	>135	$mg\,kg^{-1}\,d^{-1}$	

Chronic.

Rat (2-year feed)	ca. 5	$mg\,kg^{-1}\,d^{-1}$	
Dog (2-year feed)	ca. 2.8	$mg\,kg^{-1}\,d^{-1}$	
Mouse (18-month feed)	ca. 114	$mg\,kg^{-1}\,d^{-1}$	[23, p. 480]

ADI: $0.013\,mg\,kg^{-1}\,d^{-1}$ [23, p. 840]

7.9.18. Miscellaneous Herbicides

Bispyribac-sodium [*125401-92-5*], [23, p. 129]

LD_{50} (rat, oral)	2635 – 4111	mg/kg
LD_{50} (rat, dermal)	>2000	mg/kg
LC_{50} (rat, 4-h inhalation)	>4.48	mg/L air

Rabbit: nonirritating to skin
Rabbit: slightly irritating to eyes
Nonmutagenic (Ames test)
NOEL/NOAEL
Chronic.

Rat (2-year feed)	1.1	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	1.7	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.011\,mg\,kg^{-1}\,d^{-1}$

Butroxydim [*138164-12-2*], [23, p. 167]

LD_{50} (rat, oral)	1635 – 3476	mg/kg
LD_{50} (rat, dermal)	>2000	mg/kg
LC_{50} (rat, 4-h inhalation)	>2.99	mg/L air

Rabbit: moderately irritating to skin
Rabbit: mildly irritating to eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL
Teratogenicity.

Rat (gavage)	5	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	15	$mg\,kg^{-1}\,d^{-1}$ (developmental)

Chronic.

Rat (2-year feed)	2.5	$mg\,kg^{-1}\,d^{-1}$
Dog (1-year feed)	5	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	10	$mg\,kg^{-1}\,d^{-1}$

Cafenstrole [*125306-83-4*], [23, p. 173]

LD_{50} (rat, oral)	>5000	mg/kg

7.10. Economic Aspects

In 1997, herbicides accounted for 49 % of the world agrochemical market, with an end user value of US $ 14.76×10^9 [172]. When the herbicide market is considered according to its chemical classes, the amino acid derivatives made up 18 % of the total herbicide market, followed by sulfonylureas (10.8 %), triazines (8.5 %), amides (7.5 %), imidazolinones (6.7 %), aryloxyphenoxypropionates (5.4 %), bipyridyls (5.0 %), toluidines (4.8 %), ureas (4.3 %), carbamates (4.2%), hormones and diazines (3.2 and 3.4 %, respectively), diphenyl ethers and pyridines (each 2.8 %), cyclohexanediones (2.0 %), benzonitriles (1.4 %), and others (8.7 %).

7.11. Regulatory Aspects of Pesticide Residues

Because herbicides represent a powerful tool that can sometimes have detrimental as well as beneficial effects, their introduction and use must be regulated. A wide range of regulatory systems is used around the world, varying from one country to the next. Many countries, particularly the more highly developed ones, have stringent requirements related to the introduction and use of pesticides, but a complete discussion of these is beyond the scope of this article. Therefore, the following discussion will be limited to procedures applicable in the United States, representative of countries with extensive and rigorous systems.

The registration of new pesticides is administered by the Environmental Protection Agency. This agency establishes policies and requirements, and reviews environmental, toxicological, and analytical data submitted to support registration of a product. The Food and Drug Administration monitors residues of commercial pesticides that may be present in the food supply.

Many extensive studies are required to support an application for registration of a new pesticide. Those include: analytical methods; storage stability; metabolism in plants, animals, and soil; general behavior in soil, including leaching, adsorption, evaporation, photodecomposition, and degradation; identification and quantification of residues in food and feed products; interaction with activated sludge products; and an extensive array of toxicology tests. Completing all the mandatory studies requires several years and many millions of dollars.

If the product in question is to be used on food or feed, a legal tolerance must be established. The legal tolerance is the maximum amount of pesticide legally permitted on a commodity as it travels in commerce. An example of general procedure of this type is outlined in Figure 18.

From the toxicological data a reference dose is determined. While the reference dose is being determined, studies are being carried out in the field under the conditions of proposed usage. Residue studies must be conducted on each crop for which the pesticide is to be registered, and in each area of the country where usage will be allowed. Pesticide formulations are applied according to the proposed label using good agricultural practices. The agricultural products are then harvested at the appropriate time, and the crop is analyzed for evidence of the new pesticide. The proposed legal tolerance is generally set somewhat higher than the actual level of detected residues to allow for differences in weather or application technique as a way of making sure that a crop produced according to the label and good agricultural practices will not inadvertently contain residues above the legal tolerance. If no residues can be detected under the application conditions specified on the proposed label, a low legal tolerance is assigned to assure the user that a new instrument detecting tiny amounts of residue will not make such a crop illegal sometime in the future.

Dietary exposure estimates are then developed based upon the level of the proposed legal tolerance using the tolerance assessment system (TAS). This is a computerized system that includes many subgroups established according to estimates of the dietary intake of that particular crop. The subgroups might include females of childbearing age, children under one year of age, specific ethnic groups, geographical population distributions, etc. The resulting dietary exposure estimate is then added to an estimate of exposure of the pesticide in question when used on other registered crops. The total exposure from all crops taken together must not exceed the reference dose. If all these requirements are satis-

Figure 18. Schematic diagram of procedures used to establish a legal tolerance

factorily met, EPA may issue a legal tolerance for the product to be used on a given crop.

This procedure incorporates a number of safety factors. The reference dose is many-fold smaller than the most sensitive no-observed-effect level (NOEL). If residue levels in treated crops are undetectable or very small, the dietary exposure may be tens or thousands of times lower than the reference dose. In estimating dietary exposure, an assumption is made that every hectare of that particular crop in the country is to be treated with the herbicide under consideration at the maximum recommended dosage, and that every treatment will result in a residue equal to the legal tolerance. These assumptions are essentially never accurate. Moreover, residue levels are measured in raw agricultural products, but residues often are reduced by processing, washing, or cooking. All of these factors combine to provide considerable assurance that pesticide residues in the food supply will not be harmful.

However, there remain certain unavoidable weaknesses in the system. The NOEL is based upon tests on animals, not humans. It is impossible to determine a NOEL level for every possible combination of different pesticides. Some individuals might be highly sensitive to low doses of any substance, including pesticide residues.

The Departments of Agriculture in the various states become involved in monitoring and enforcing regulations on pesticides in their respective states. Pesticides are divided into those for general and restricted use. Restricted pesticides may be sold only to individuals who have received appropriate training, and who have passed an examination in pesticide usage. Consultants, government employees, and commercial applicators must receive more extensive training, and successfully complete correspondingly more rigorous examinations.

Regulations may also extend to such peripheral activities as transport, application technology, storage, and container disposal.

As a result of the large investment in both time and money associated with registration of a new pesticide, pesticides are seldom introduced unless the manufacturer can expect to acquire a significant fraction of the market associated with such extensive crops as maize and soybeans. Registrations for minor, low-volume crops are more difficult to obtain, most products certified for minor crops are ones that have already been registered in conjunction with major crops.

Another disincentive with respect to a manufacturer's registering compounds to be used on low-volume crops, especially high-value ones, is the threat of liability. If sales for a minor crop prove relatively small, even one lawsuit might cost the manufacturer more than the total profits earned from many years of sales.

The question as to whether the existing extensive requirements and regulatory measures are adequate to protect the general public depends largely on one's point of view. Some people insist on zero risk unless a compelling direct benefit can be established. Others consider the risks associated with pesticides to be small and acceptable. A number of countries in the world still lack rigorous regulatory agencies, and the corresponding risks to the environment and to the local population are considerably higher than those in much of the developed world.

8. General Comments

Controlling weeds has been a major problem since agriculture began. Besides agriculture, there are many other situations in which vegetation management is important. New techniques for controlling weeds have developed over the centuries, while few of the old techniques have been discarded. There is wide agreement among weed scientists that the use of a combination of methods is far more efficient and sustainable than dependance on only one. Relying on any one method – tillage, flooding, chemicals, even hand-weeding – can lead to a rapid shift to species that are tolerant of that method, or to the development of tolerant subtypes within a normally sensitive species.

The development of highly effective and selective herbicides, primarily since the 1940s, has resulted in an enormous improvement in the ability of vegetation managers to control unwanted plants. Weeds can be controlled faster, more cheaply, and arguably more safely than with machetes, mowers, or fire, but the use of herbicides often is not looked upon with favor.

As with any method, herbicides of course present some risks. They constitute a powerful tool, and it is impossible to say with complete assurance that they might not influence the environment in some detrimental way perhaps 20 years in the future. One cannot ever prove a negative proposition. There might certainly be some few people who are extremely sensitive to small amounts of herbicides in the environment or food. And, of course, exposure from accidents is a potential cause of physical damage, and nontarget plants may be damaged from soil residues or from drift.

Many scientists believe that the risks associated with pesticides are small and often exaggerated. Rotary mowers that can throw rocks and other projectiles a considerable distance may pose a significant hazard, but people understand this, and become accustomed to their use. On the other hand, herbicides are invisible and largely misunderstood, and very few people are aware of the safeguards already in place in the registration process. In fact, the toxicity of natural components in the food supply almost certainly exceeds by a wide margin the potential toxicity from herbicide residues.

The hazards due to herbicide use must be compared to the hazards connected with the alternative methods, including doing nothing. Doing nothing is not risk-free when one takes into account traffic obstructions, poisonous plants, and dermal and respiratory poisons in weeds, to say nothing of potential economic damage.

The most efficient weed control results from an intelligent combination of all the appropriate methods. Herbicides can play an important role in the process if used wisely.

1. Definitions

Welding is defined (DIN 1910, Part 1: 07.81 and ISO 857: 1990) as the bonding of several parts made of the same or different materials to form a single unit, where, in the weld region, either the temperature is raised to the melting point, the parts are pressed together, or both. Weld filler materials are also used as necessary. The welded joint can be separated only by destroying it. This definition applies to the welding of both metals and thermoplastic materials.

In most welding processes, the materials are in the molten state where they become joined in the weld region; in a small number of widely used processes they are in the plastic state. When the two workpieces are made of the same material, the properties of the cooled weld are similar to those of these materials. When the materials are different, the welded joint generally behaves like a mixture of the two.

Welding is also considered to include weld overlay cladding, roll cladding, and explosive cladding. Here, material that can be the same as or different from that of the workpiece is applied to an area of the surface of the workpiece by welding. Cladding with the same material is usually reserved for repair purposes, while cladding with a different material is used to protect the parent metal from wear or corrosion. The methods of welding metals can be divided into two groups:

In *fusion welding* of metals, the junction area is melted to form a pool of molten metal which consists of parent metal, either alone or with added filler metal (minus metal lost in the process). The zone surrounding the molten pool is to a greater or lesser extent affected by changes to its structure and properties, depending on the degree and duration of heating and the rate of cooling. This depends on the heat flux, which in turn is very dependent on the welding method.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_203

In *compression welding* of metals, the workpieces are pressed together at the welding region, and, in most processes, are also heated. The heat is applied by various means, e.g., electrically (resistance or induction heating), or by flames.

In *friction welding*, the heat is generated by friction between workpieces pressed together and sliding relative to each other.

In *explosive cladding* (see → Corrosion), the very high kinetic energy of detonation of the explosive material is transformed into a plastic impulse (and only to a very limited extent into heat) as the sheet of cladding material is impelled almost perpendicularly onto the parent metal. The relatively small increase in temperature, combined with the very high explosive pressure, leads to plastic deformation (which advances with the detonation front) of the thin layers brought into contact, and forms a weld with wavelike indentations.

Welding of thermoplastics (→ Plastics, Processing, Chap. 3.2.1.) is similar to pressure welding of metals. Welding temperatures are low because of the nature of the material, which is normally softened until it exhibits plastic flow. Various theories have been proposed regarding the processes that occur in the weld zone [12].

Cutting of metals is the opposite of welding. It consists in producing a gap by a fusion process. The various methods of generating the necessary heat characterize the three cutting processes:

In the *burning* process, the cutting point moves, material is heated to its ignition temperature, part of it is burnt to form metal oxide by part of the oxygen stream, and cutting follows immediately, the molten material being blown away from the gap by the rest of the oxygen.

In *plasma cutting*, electrical energy causes partial dissociation and ionization of a gas stream to form a plasma stream which then transfers most of its energy to the workpiece.

In *laser cutting*, the laser beam – monochromatic light focused to give a high energy density – is absorbed by the workpiece. Laser cutting in particular causes the material not only to melt, but also partially to vaporize. A supplementary gas stream drives the molten material out of the gap formed. Only laser cutting is suitable for cutting plastics, most of the material removed being vaporized.

2. Fundamental Principles

2.1. Weldability

A component fabricated by welding is weldable if, after fabrication, it fulfills all the functions required of it at its point of use for the duration of its expected lifetime. It is not weldable if it does not fulfill these functions as a result of any defects arising from a welding process. Weldability (see DIN 8528, Part 1: 06.73) does not depend solely on the materials used. Each welded component is made by welding together several smaller components, possibly made of different materials.

The following considerations influence the design (e.g., wall thickness, arrangement, and form of the welded joints) [13]; these are not always independent:

1) The functions of and stresses on the welded component at its operating temperature during its lifetime
2) The physical and metallurgical properties of the material used for the component (determined by its chemical composition and method of manufacture)
3) The welding method or methods and associated processes (e.g., preheating, controlled cooling during welding, and subsequent heat treatment) used to produce the welded component

One of the most important preconditions for a good welded joint is that impurities on the surface of the workpiece such as thick scale, rust, oil, and paint should be removed as completely as possible. It is certainly possible to weld over a protective coating, but this can affect the integrity of the weld.

2.2. Details of Welding and Cutting Processes

In fusion welding, pressure welding, and fusion cutting, the workpiece is heated at the point of the operation. The rate of heat flow to the workpiece being welded or cut determines the temperature changes and temperature distribution within the workpiece. This heat flux brings

the metal to its melting point where the welding is to take place. In the subsequent process of solidification, crystallites grow from the cooler regions outward (usually starting from the parent metal). This solidification structure is always surrounded by a zone of parent metal that is affected by heat. The extent of the fusion zone and heat-affected zone depend on the method used. In pressure welding, unlike fusion welding, the workpiece is not only heated, but the components are pressed together in accordance with a given pressure – force – time regime. Thus, there is not only a change in the metallic structure (recrystallization) due to heating, but a superimposed structural change due to deformation, and a characteristic "worked" structure is formed.

The metal used for filling the gap or cladding the parent metal must be compatible with both the parent metal and the welding process, must be appropriate to the form of the semifinished product used (e.g., rod, wire, or strip), and must be applied in a suitable manner, e.g., in a small number of comparatively thick welding beads or in many thin beads, in order to achieve the objective of the welding operation. The mixing effect of the welding operation may be required to affect a large or a small volume [14, 15]. Desirable metallurgical effects, such as annealing due to multiple welding passes, as well as the effects of possible reactions (usually undesirable) between the components of the workpiece in the fusion region of the weld and the surrounding gaseous atmosphere (flame gases, gases from the welding rod coating or welding powder, or the air) or the molten slag lying above it, must be considered and steered in a favorable direction. The temperature profiles and temperature changes during welding and subsequent solidification are also important. It is not usually possible to ensure satisfactory welding by using filler metal that is identical to the parent metal.

As the composition or structure (or both) of the material [16] in the weld bead is always different from that of the original parent metal, the properties of the weld bead differ from those of the parent metal. Also, in the heat-affected zones of the unmelted parent metal on both sides of the weld, changes to the structure and hence to the properties take place as a result of heating. The extent of these changes is determined by the original structure, the heating rate, the time for which temperatures are maintained, and the cooling rate. The parent metal is least affected by the welding operation if this is rapid and the volume of fused material is small. High-power welding processes therefore conserve the properties of the material better than conventional processes.

Finally, heating and melting lead to expansion, and solidification and cooling to contraction. These volume changes lead to interior stresses in the welded component if deformation is prevented, but if the interior stresses exceed the elastic limit of the material, permanent deformations are produced.

All these effects determine the performance of the welded component under operating stresses, so that, when selecting the welding process, not only the type of material and wall thickness must be considered, but also the stresses that the finished welded component is likely to undergo.

In fusion cutting, the effects on the material are similar to those caused by welding, as here, too, localized areas of the material are heated strongly and rapidly, and cooled equally rapidly. In cutting processes by both burning and plasma methods, the gap formed is swept clear by a high-velocity gas stream. The type of gas used influences the reaction in the molten metal, and sometimes also that in the surface region near the gap. Laser cutting creates a gap, even without auxiliary gases, but a higher rate of cutting metals is achieved if oxygen is used, as this oxidizes the metal and sweeps the gap clear. Nitrogen is usually used when laser cutting flammable thermoplastic materials, to extinguish the flames.

A basic rule applies to all fusion cutting processes; higher energy density processes lead to smaller heat-affected zones in the parent metal.

2.3. Influence of Physical and Chemical Properties

2.3.1. Material Properties

The chemical composition of a metallic material, including any impurities present, determines its properties and the changes to these properties that will take place on welding and cutting, and also the performance of the finished welded or cut zone when the component is put into service. The welding or cutting

method should be selected according to the melting method, the time spent at high temperature, the solidification time, etc.

The material most commonly welded is steel, and, as the properties of this material can be modified by a wide range of influences that lead to slight changes in its chemical composition, it is used here to illustrate the most important of these influences. Other metallic materials show analogous behavior. Recommendations for the welding of alloys are given in Chapter 5.

1) The percentage of carbon in the steel determines its hardening properties.
2) The principal alloying elements in the steel (chromium, nickel, molybdenum) determine the critical cooling rate and hence the extent of through tempering.
3) The number of seed nuclei (e.g., aluminum, titanium) and the extent of deformation and recrystallization determine the microstructure. This is of decisive importance for the strength and toughness properties.
4) The presence of a high concentration of seed nuclei can have a better grain refining effect on the material than the melting process.
5) The chemical composition also influences remelting and solidification, the viscosity of the melt, and the wetting properties, and hence the formation of the solidified welding pool.
6) Hot cracking is mainly caused by impurities (mainly sulfur).
7) Reaction with the environment (e.g., corrosion, scale formation, uptake of foreign gases) is also a function of the chemical composition of the material.

Other important properties include segregation behavior, the nature and formation of nonmetallic inclusions, and the anisotropy of the solid (which is increased by hot working).

The physical properties of a material also influence its weldability. These include its coefficient of thermal expansion, thermal conductivity, specific heat capacity, melting point and melting range, hardness, and toughness. These properties depend on the chemical composition and sometimes the preceding heat treatment of the workpiece. Components that have been manufactured in preparation for welding have already been subjected to heat treatments such as annealing, tempering, solution annealing, or solution annealing and hardening, and may also have been cold-hardened by forging, rolling, or drawing. These initial conditions are more or less disturbed by the welding process, especially in the region of the fusion zones and the neighboring heat-affected zones.

Most plain steels and austenitic steels can be welded without significant changes to their properties, and do not require subsequent heat treatment. Steels with good hardening properties and tempering steels are heated after the welding process to remove hard spots. Hardenable steels can also be welded if they are first preheated and then welded, slowly cooled, and annealed. Steels which can be solution hardened may regain their hardness after welding if they are welded in the solution-annealed and hardened state and subsequently aged, or if they are welded in the solution-annealed state and subsequently hardened.

If shrinkage is prevented during cooling after welding, a heat treatment is required to relieve interior stresses. The severity of these stresses is also a function of the design of the welded component and the welding sequence used in the fabrication process.

To sum up, the chemical composition of a workpiece is of critical importance for its weldability.

2.3.2. Design of Welded Components

At the planning stage, welded products, especially if they are likely to be highly stressed, should be designed so the welds are placed in areas of low stress as far as possible. Welds should be located where there is a minimum change of cross section at the junction between the workpieces to be welded. The welds should nevertheless be easily accessible. The materials of the workpieces (parent metals) should be easily welded together, and the filler metal should be similarly compatible with the parent metals. As costs of welded components are always important, compromises are often necessary.

These requirements must be matched to the welding process used, including preparation of the surfaces to be welded and of the neighboring material. The sequence of the various welds or cutting operations must also be established.

If different materials are welded together, e.g., austenite – ferrite joints, other measures are sometimes necessary, to guard against increased sensitivity to corrosion or the effect of differences in heat transfer coefficients, etc. These effects and the diffusion of individual components of a material into other materials at high service temperatures can be minimized by including intermediate welded layers. When welding pipelines in which the components have different carbon contents, intermediate welded layers (e.g., nickel alloy) are included to prevent diffusion.

Consideration should also be given at the planning stage to the necessity for later treatment of a welded component, e.g., by stress relief heat treatment (support to prevent collapse is sometimes necessary) or by pickling (draining off of pickling solution must be considered). Also, the welds or the complete welded item may need to be tested after finishing. Tests may include: approval of the combination of materials by organizations such as, e.g., the TÜV in Germany, testing of pressure vessels, determination of tensile strengths and notched-bar impact values of the welded joint, or X-ray or ultrasound testing of the weld. To ensure problem-free fabrication of welded components, the process must be suitable and the personnel concerned must be trained.

In addition to the preparation of the joint to be welded, it is also necessary to remove harmful materials on the surface (dirt, rust, and oil). Auxiliary materials must be kept dry and protected from oxidation; coated electrodes and powder for powder welding must be stored under dry conditions. These auxiliary materials may sometimes need to be dried before welding is carried out.

3. Welding Processes

Welding processes can be divided into three main groups:

1) Fusion welding (Fig. 1)
2) Pressure welding (Fig. 2 A)
3) Other processes (Fig. 2 B)

The methods most widely used in the chemical industry are gas welding, manual arc welding, various gas-shielded welding methods, and submerged arc welding, all members of the first group.

3.1. Fusion Welding

3.1.1. Manual Gas Welding (Autogenic Welding)

In manual gas welding [17, 18], the heat required is produced by burning a mixture of fuel gas and oxygen. The only fuel gas used is acetylene. The flame impinges directly on the welding area, and the filler metal is fed by hand.

There are two types of manual gas welding [1, p. 233]:

1) The filler wire is fed in the direction of welding, preceding the welding torch (leftward welding, with the torch held in the right hand)
2) The filler wire is fed in the direction of welding, following the torch (rightward welding)

Leftward welding is used for sheet metal thicknesses ≤ 3 mm, and rightward welding, which is used when penetration to the root of the joint is very important, for thicknesses >3 mm. Rightward welding produces a "key-lock" or "hook-and-eye" formation, enabling penetration to be controlled visually during welding.

In manual gas welding, the rate of heat flow to the workpiece is low compared with other welding methods, and the process is comparatively slow. For this reason, and because of the high thermal conductivity of metal, the structure of the neighboring parent metal is considerably affected. In spite of its disadvantages, ca. 10 % of all welding is by the autogenic method.

The autogenic torch is simple, lightweight, and cheap. It is much used for repairs and for simple jobs in the workshop. The gas supply consists simply of oxygen and acetylene bottles with tubing to convey these gases to the welding area. The main uses of autogenic torches are for welding pipelines in chemical plant construction, general industrial plants, shipbuilding, and heating plants, where its value depends more on the manual skill of the welder than on high melting rates.

Gas supplies for fixed welding machines for series production are usually from fixed oxygen and acetylene ring mains in which the oxygen

Figure 1. Fusion welding processes

is fed from banks of bottles or cryogenic gasifiers, and the acetylene from banks or bundles of bottles, or from larger transportable gas supply equipment.

Acetylene is used exclusively as the fuel gas in gas welding, as of all the hydrocarbons it has the highest heat of formation per unit mass, and gives the highest combustion temperature (Fig. 3), combustion rate, and hence heat flux and heat transfer from the flame to the workpiece. This is especially useful for the rapid heating of small surfaces. To prevent scaling and decarburization of the workpiece, the acetylene flame is adjusted to a neutral state, i.e., with no excess of either oxygen or fuel gas (volume ratio of oxygen to acetylene ca. 1.05). The rest of the oxygen required by the stoichiometry is provided by the surrounding air.

3.1.2. Arc Welding

In arc welding [19, 20], the heat source is the electric arc between the welding electrode and the workpiece. The arc may be exposed, but is then nearly always surrounded by a gas shield (see below), or it may be covered by a layer of powder (submerged arc welding). In both cases, access of air (oxygen, nitrogen, and water vapor) is restricted.

Protective gases (→ Protective Gases, Chap. 5.) [1, p. 263] are either inert (almost exclusively argon), reactive (carbon dioxide), or mixed gases with a high proportion of inert gas, e.g., argon, and 1 – 9 vol % oxygen or ≤18 vol % carbon dioxide. These not only have a protective effect, but in some cases a metallurgical effect also.

Welding powders used in the submerged arc process (DIN 8557, Part 1: 04.81 and EN 756: 1992) stabilize the arc and reduce the rate of heat loss and also have a protective effect. Metallurgical effects include deoxidation, prevention or replacement of burn-off losses, and sometimes addition of alloying elements. The powders consist mainly of oxides of silicon, manganese, calcium, barium, magnesium, titanium, sodium, potassium, and iron, and also some fluorides, e.g., of calcium and sodium/aluminum. The many types of powder can be classified according to their

Figure 2. Pressure welding (A) and special welding (B) processes

principal components (manganese silicate type, calcium silicate type, basic aluminate type, etc.).

The electrical energy is fed to the arc from controllable and variable sources of electric current, e.g., transformers, rectifiers, or converters. Arc welding processes operate at a higher heat flow rate then gas welding, so that higher welding and melting rates can be achieved and the heat-affected zones are less extensive.

Manual Arc Welding. In manual arc welding with coated electrodes, the arc is formed between the melting end of the electrode and the workpiece, causing the coating to melt and partially vaporize. The weld pool and the molten droplets during transfer to the workpiece are protected from the surrounding air by the gases produced from the coating.

The coating also performs a number of other functions:

1) It facilitates metallurgical reactions that clean the weld pool
2) It stabilizes the arc
3) It compensates for the loss of alloying elements from the cored wire and the parent metal
4) It can introduce seed nuclei into the weld pool and hence grain refine the weld metal
5) It can control the basicity or acidity of the melt
6) It can alloy with the material of the welded joint and hence modify its chemical composition

The electrode coating [21] can form a tough skin on the weld pool. This is useful when welding in difficult situations, e.g., overhead, as it precents low-viscosity constituents of the weld pool from running off. When welding in normal situations, the tough skin improves the appearance of the surface of the weld bead.

Figure 3. Temperature profile along the flame axis when burning acetylene and propane

A suitable electrode coating composition can also make the weld bead less likely to form edge notches, and the presence of reducing agents in the coating can reduce the harmful effects of partial scaling and of protective coatings on the sheet metal surface. The coating should also form a layer of slag that is easily removed after solidification, or even breaks away spontaneously.

It is often impossible for the various components of the electrode coating to perform all the many different functions desired of it.

Cored wire is usually used to achieve a composition that matches that of the alloy being welded as closely as possible. The special requirements of manual electrodes are met with the aid of the coating used. The coatings on manual welding electrodes have compositions similar to those of submerged arc welding powders, and usually contain silicon, manganese, calcium, titanium, magnesium, aluminum, potassium, and sodium, as well as gas formers such as cellulose for certain applications.

Electrodes classified according to each individual range of requirements (DIN 1913, Part 1: 04.84 and EN 499: 1992). Two extremely important types of steel electrode are:

1) The rutile (titanium dioxide) type with a high proportion of titanium dioxide in the coating, with which simple manual welding tasks can be quickly carried out
2) The basic lime (calcium carbonate) type with a high proportion of calcium carbonate in the coating, which can produce welds with the best quality characteristics, especially toughness

High-performance electrodes have coatings containing a high proportion of metal in powder form. These give a higher melting rate than normal electrodes for the same electricity consumption.

Welding with Cored Wire. Cored wire is a tubular metal electrode filled with material similar to that used for the coating on normal electrodes. Its particular advantage is that it can be fed from a long coil, and can be welded continuously. This gives a faster average welding speed than with manual electrode welding. During welding, the cored wire slides through a burner close to the welding area. Shielding gas can also be injected. The use of cored wires containing gas-producing substances can enable welding to be carried out without a gas shield under difficult conditions, e.g., in wind.

Figure 4. Principle of TIG welding
a) Tungsten electrode; b) Filler metal; c) Electric arc; d) Shielding gas; e, f) Workpieces

Tungsten Inert Gas (TIG) Welding. In these processes (Fig. 4), the arc is formed between the tip of an infusible tungsten electrode and the workpiece. The function of the electrode is only to conduct electricity and produce the arc. The filler metal is fed to the weld pool from one side, either by hand in rod form or by an automatic system as wire. Argon is usually used as the protective gas, occasionally helium or argon – helium mixture. The tungsten electrode is

alloyed with up to 4 % thorium dioxide to reduce the work of electron emission at the tip of the electrode and to increase the maximum current.

Welds of the highest quality can be produced by TIG welding. It is best to use direct current with the workpiece as the positive pole when welding high-alloy (chromium – nickel) steels, nickel-based alloys, titanium, zirconium, tantalum, and their alloys. Alternating current is used when welding metals that form high-melting oxides, e.g., aluminum and its alloys, as continuous reversal of the current direction continuously removes the oxide film from the weld pool.

Pulsed current arc welding is a variation of the TIG process. This is very useful for welding thin sheet metal, as it minimizes the extent of the heat-affected zone and hence the distortion of the sheet. The weld pool is so small that dripping of molten metal does not occur, even when welding in difficult situations. For high-quality TIG welding, transistorized pulsed current welding robots are available that can be very precisely controlled by a variety of computer programs. A pulsed current TIG weld bead is illustrated in Figure 5.

Figure 5. Weld bead produced by the TIG process
Pulsed technique; 2-mm thick Cr – Ni sheet; square butt joint without filler metal
A) Top view; B) Polished section

Plasma Welding. With the plasma arc, the gas rate is usually much higher than with the TIG arc [22–24]. Also, the temperature of the arc is increased by a factor of 2 – 4 and the energy density by a factor of ca. 10. This is achieved by greatly constricting a TIG arc together with the protective gas stream surrounding it with the aid of a water-cooled copper nozzle, forcing the entire gas stream to pass through the arc (Fig. 6).

Figure 6. Principle of plasma welding
a) Electrode (negative); b) Water-cooled copper nozzle, electrically isolated from cathode; c) Plasma jet; d, e) Workpieces

Figure 7. Polished section of weld bead produced by the plasma jet process
5-mm thick Cr – Ni sheet; square butt joint without filler material

In plasma welding, the plasma jet is always surrounded by a protective gas layer. As the plasma jet usually penetrates into the sheet, the result is a key-lock effect (Fig. 7) similar to that produced by autogenic rightward welding.

There is an upper limit to the weldable sheet thickness, but the welding speed is significantly higher than in other arc welding processes. The amount of heat applied per unit length of weld is small.

A very wide range of power outputs can be used in plasma welding, and the process can therefore be used for sheet thicknesses in the approximate range 0.01 – 10 mm. So-called microplasma welding is a low-power process using an "untransferred" arc, i.e., between the tungsten electrode and the nozzle wall. In the medium to higher power range, the plasma welding arc is "transferred," i.e., it is between the tungsten electrode and the workpiece. The usual plasma gases are argon and hydrogen.

Plasma welding is also used for resurfacing metal, which can be plated over large areas to a thickness of ca. 2 – 8 mm. It is mainly used in the construction of chemical equipment. There are two variations: plasma welding of powder coatings and plasma welding of wire.

In plasma welding of powder coatings, the powder is fed from a holding vessel to the plasma stream, where it melts. In the hot wire process, two wires are fed in parallel to the welding zone. Electric current from an auxiliary source is passed through the wires, heating them (because of their ohmic resistance) to a temperature just below their melting point close to the welding zone. The plasma burner oscillates and can therefore apply metal to a wide fusion zone.

Metal Inert Gas (MIG) Welding. In MIG welding [19], a high-power process, the arc is produced between a wire electrode, fed from a coil, and the workpiece. This method of supplying the electric current gives a high electrode current density (ca. 100 A/mm^2) and hence a high melting rate.

The wire electrode is fed to the electric arc by a motor whose speed can be varied according to the wire diameter and electric current (Fig. 8). The current to the welding wire is fed through a tubular contact in the "welding pistol" close to the arc. Only direct current is used in the MIG process, the electrode usually being the positive pole. The metal is then transferred as small droplets and penetration is deep. If the electrode is negative, larger drops of metal are transferred and there is less penetration.

Figure 8. Principle of MIG/MAG welding
a) Coil of wire; b) Wire electrode; c) Gas shield; d) Electric arc; e, f) Workpieces; g) Electrical contact device

There are two variations of the process [25]:

1) The metal inert gas (MIG) process, in which an inactive, i.e., noble gas shield is used
2) The metal active gas (MAG) process in which the protective gas is active, e.g., carbon dioxide or mixtures or argon with carbon dioxide and/or oxygen

Figure 9. Polished section of a double fillet produced by the MAG process
5-mm thick St 37-2 steel plate; shielding gas 90 % argon, 5 % CO_2, 5 % O_2

The MIG process, with argon (or sometimes helium) as the protective gas, can be used to weld workpieces of thickness >3 mm made of nonferrous metals and alloy steels. With pulsed direct current of variable magnitude and pulse frequency, the transfer of droplets can be controlled. In this pulsed arc or pulsed MIG process, each pulse of current causes a droplet of metal that has been melted in the background current

Figure 10. Portable TIG welding machine (inverter, courtesy of Oerlikon, Eisenberg)

Figure 11. MIG/MAG pulsed welding machine (courtesy of Oerlikon, Eisenberg)
Maximum 400 A at 60 % operating duty factor

phase to be thrown off. The droplet size and frequency can be influenced by the type of pulse used. The pulsed MIG process is very suitable for welding in difficult situations.

The MAG process is mainly used for welding plain carbon and low-alloy steels. As the protective gas has an oxidizing effect, the filler metal must contain a high proportion of deoxidizing components (e.g., manganese, silicon, aluminum). The metallurgical reaction that takes place gives increased nucleation and hence grain-refined weld metal. A double fillet weld made by the MAG process is illustrated in Figure 9.

Sources of Electric Current. Power transistors are increasingly used for controlling the electric current. They can be used as digital switches or analog regulators. As their power losses are higher, analog regulators are used mainly for lower-power equipment. As switches (high frequency), they can be in the primary or secondary circuit, i.e., the transistors can be between the mains supply and the transformer or the transformer can be between the mains and the transistors. With the first arrangement (Fig. 10), the equipment is lightweight, but very sensitive to voltage peaks. Equipment of the second type (Fig. 11) is heavier.

Submerged Arc Welding. In submerged arc welding, the arc produced between the automatically fed filler wire and the workpiece (Fig. 12) is covered by powder, and is located in a cavity formed within powder that has become molten [26]. The powder flows in the direction of welding, preceding the welding zone of the metal sheet. Only a small amount of powder is consumed by the welding process, and the unused powder is sucked away and reused. The powder blanket essentially performs the same function as the coating on manual electrodes. The welding speed is high, and in equipment with several filler wires the melting capacity is also high. The process can be used only in situations where the sheet metal is not steeply sloped. A weld pro-

duced by this process is shown in Figure 13, and a coating of weld metal in Figure 14.

Narrow Gap Welding. Heavy section workpieces can be joined economically and with minimum effect on the parent metal by the so-called narrow gap welding process. The best of the various methods for filling a vertical narrow gap with weld metal is the MIG/MAG process. In this gas-shielded process, the filler wire and protective gas are cooled in a sword-shaped sheathed tube and fed to the welding point in the narrow gap. There are two systems:

1) Two wires, which have been subjected to plastic deformation to give a predetermined internal stress, are guided into the two corners of the welding gap, giving a defect-free root position
2) In the second system, this function is performed by a wire preformed to a waved shape so that it alternately fills each corner of the region to be welded inside the narrow gap

Figure 15. Narrow gap weld (vertical gap)
Metal ASME SA 387, group 22; metal thickness 300 mm; gap width 9 mm; welding speed 220 mm/min; 76 weld passes

Narrow gap welding can also be carried out by the submerged technique. While gas-shielded narrow gap welding can be used for gap widths

of ca. 10 mm (Fig. 15), the gap must be wider for submerged welding.

3.1.3. Electroslag Welding

Electroslag welding is a machine-operated resistance-heated fusion welding process for joining vertical metal plate >20 mm thick (Fig. 16). The filler metal is fed from above in wire form and melts in the molten slag layer. The electrical resistance of the slag layer causes heat to be generated by the current, heating and fusing both the wire and the side walls of the metal sheets being joined. The current passes through the filler wire to the slag layer. Water-cooled copper plates, which are moved upward as welding proceeds, retain the weld pool and give a constant weld thickness. The weld section is filled in a single pass. As the weld pool is comparatively large and the cooling rate is slow, a coarse metal structure can be formed; iron powder or additional cold wires are added to counteract this effect.

3.1.4. Electron Beam Welding

In electron beam welding (Fig. 17) [27, 28], the energy source is an electron beam with a high energy density (up to 10^8 W/cm^2). The electrons are emitted from an incandescent tungsten or tantalum cathode in a vacuum of ca. 1.3×10^{-2} – 1.3×10^{-3} Pa (1.3×10^{-4} – 1.3×10^{-5} mbar), accelerated by a high voltage (up to 150 kV), and focused by electromagnetic lenses to a narrow beam. The electrons penetrate the workpiece at high velocity, and a high proportion of their kinetic energy is converted to heat. This region of the workpiece melts, and the metal at the center evaporates, so that a metal vapor capillary is formed, surrounded by an envelope of molten metal. As the energy is released almost uniformly across the whole thickness of the sheet (deep welding effect), an extremely narrow, needle-shaped melting zone is formed (Fig. 18). The heat-affected zone in the parent metal is very small.

Figure 17. Electron beam welding machine
Vacuum chamber for individual welding of large components with complex weld geometries, e.g., turbine wheels (courtesy of Messer-Griesheim)

The wide range of weldable metal thicknesses, from foil with a thickness of micrometers to plates over 100 mm thick, is not matched by any other process. The deep welding effect of the

electron beam enables welds to be produced at high speeds where access is very difficult, e.g., in deep recesses.

Electron beam welding is used in the construction of equipment and machinery, and in aircraft technology. As the process is operated in a vacuum, it can be used to weld gas-sensitive, high-melting, and chemically active metals such as tungsten, molybdenum, tantalum, nickel, zirconium, titanium, and special high-temperature steels. The process is also used for welding combinations of different materials and for dimensionally accurate low-distortion welding of machined precision components.

Figure 18. Polished section of a weld produced by the electron beam process
Metal Ck 45; wall thickness 40 mm; width of weld bead ca. 2 mm; width of heat-affected zone ca. 1.5 mm

3.1.5. Laser Beam Welding

In laser beam welding [27, 29], a laser produces coherent monochromatic light beams with low divergence. These beams can be focused with lenses or concave mirrors to give a power density in the focal spot of up to 10^8 W/cm^2.

Solid state lasers with power outputs of a few watts can be used for welding, but CO_2 gas lasers in the kilowatt range are more usual. The various types of laser differ with respect to the wavelength of emitted light, efficiency, and mode of operation (pulsed or continuous).

In the CO_2 laser, emission is excited by an electrical glow discharge in the laser gas, a mixture of carbon dioxide, helium, and nitrogen, and is contained in a discharge tube. This is an optical resonator, containing plane parallel mirrors at each end. One of these is semireflecting, so the laser beam passes through it and out of the laser (Fig. 19). The efficiency of the CO_2 laser is comparatively high, 15 – 20 %. The energy of the beam absorbed by the material is converted to heat. The absorption depends on the wavelength of the laser beam and on the properties of the metal and its surface.

Figure 19. A CO_2 gas laser for metal working (cutting, welding, hardening, remelting)

Figure 20. High-power CO_2 laser with maximum output 6 kW (courtesy of Trumpf)
Resonator formed into two squares on two levels; excitation by high frequency

An important advantage of laser welding is that the heat-affected zone is extremely small, so the workpiece is hardly distorted at all. As the heated zone is so thin, weld preparation must be precise and the beam must be precisely controlled during welding.

Laser welding (and cutting) has been developed into a high-power process, and is a likely candidate for industrial-scale production. Most equipment operates at power outputs of 3 –

6 kW (Fig. 20), but considerably higher powers are also available. Achievable welding speeds, which depend on the metal thickness, are given in Figure 21. A further great advantage of the process is that it does not require a vacuum.

Figure 21. Laser welding and cutting speeds in structural steels
a) Welding speed at 6 kW; b) Welding speed at 3 kW; c) Cutting speed at 3 kW with N_2 cutting gas in special steel

3.1.6. Aluminothermic Welding

In this process, the heat required is produced by the reaction (which requires external ignition) between iron oxide and powdered aluminum. The ends of the steel components to be welded are clamped together inside a prepared closed form, and the aluminothermic powder mixture is added and ignited. The aluminum oxide formed in the reaction floats on the surface and protects the molten steel from the atmosphere. This process is mainly used for welding railway lines.

3.2. Pressure Welding

Modern pressure welding processes derive from the hammering methods used in the blacksmith's forge. The forge fire has been almost completely replaced by such techniques as electrical resistance heating in resistance welding, the electric arc, e.g., in flash-butt welding, electrical induction in induction welding, friction in friction welding, and sometimes the gas flame in gas pressure welding.

3.2.1. Resistance Welding

In resistance pressure welding [30], heat is produced by passing an electric current through the workpieces, which are in contact at the area to be welded, and the welded joint is produced by pressing them together. The electric current and compression force used, both of which may be varied during the process, depend on the nature of the weld.

Resistance Spot Welding. In resistance spot welding, flat components in contact with each other, usually sheet metal, are welded together at single points or rows of points. The welding current (nowadays nearly always alternating current) is fed through rod-shaped copper electrodes (Fig. 22). The pressure/force applied by one or both electrodes can vary with time. As the interfacial electrical resistance between the copper and workpiece materials (copper excluded) is always less than that between the workpiece materials, the spot weld is formed only between the workpiece components. In this process, only enough heat is applied to form the spot welds, so that heating effects on the parent metal are very small.

Figure 22. Principle of resistance spot welding
a, b) Workpieces; c) Spot weld; d) Copper electrodes

The force exerted by the machine must be adjusted in accordance with the thickness of the workpieces. The maximum thickness for steel is currently ca. 2×12 mm, and for light metals ca. 2×5 mm. To produce a satisfactory welded joint, the magnitude and duration of the welding current and the force exerted by the electrodes must be matched to each other for a given electrode cross-sectional area.

Spot welding can be either direct or indirect, according to the arrangement of the electrodes at the workpiece:

1) In direct spot welding, electrodes are applied to both sides of the sheet metal
2) In indirect spot welding, an electrode is applied from one side only, and the circuit is completed by a copper base

The process can be described as single-spot, double-spot, or multispot welding according to the number of spot welds produced in a single operation. In multispot welding, the strength of the joint depends on the arrangement of and distance between the spot welds. Many types of equipment and machinery are available for resistance spot welding, from small hand-operated welding tongs for a single-spot weld to the large machines used in automobile production lines.

Transistorized electric power sources are also widely used in resistance welding technology. The use of direct current for welding avoids harmful interactions with the electric network, and saves energy.

Figure 23. Principle of foil resistance roller seam welding a) Workpiece; b, c) Foil strips; d) Foil feed guides; e) Current-carrying rollers

Resistance Roller Seam Welding. In resistance roller welding, the workpieces pass between two continuously or intermittently rotating copper rollers, these being the electrodes. This system enables uniform welded seams of any desired length to be produced using a constant alternating current. Good welds are also produced by an intermittent current if the welding points overlap. One of the rollers may be replaced by a copper rail. The main application is in the production of hollow products, e.g., heating equipment such as calandrias or radiators.

In foil resistance roller seam welding, the edges of the sheet are butt welded together. On both sides of the sheet, above and below the joint, strips of corrosion-resistant metal foil are applied and welded as they are compressed between the pair of rollers (Fig. 23). Zinc-coated steel sheet can be welded with corrosion-resistant foil without reducing its resistance to chemical attack.

Resistance Projection Welding. This differs from resistance spot welding in that one of the two parts being welded is shaped to produce projections, and the electric current then becomes concentrated at these points. Several spot welds can then be formed simultaneously using simple copper electrodes with flat surfaces. This process is especially suitable for welding relatively small mass-produced components.

Resistance Butt Welding (Pressure Butt Welding). In pressure butt welding, plane parallel machined surfaces of workpiece components are pressed together, and an electric current is passed through this area with the aid of copper jaws clamped on close to the butt joint. Maximum heating occurs at the interface as the resistance is a maximum at this point. The compressive force produces a bulge during the welding operation. This process is especially suitable for very simple profiles with cross-sectional areas up to ca. 500 mm^2.

In flash-butt welding, the surfaces are not machined, and initially come into contact at a few points only. However, the whole of the interfacial area is eventually affected during the course of the welding operation. The process is used for butt welding sheet, profiles, and pipes with cross-sectional area up to ca. 70 000 mm^2.

3.2.2. Arc Pressure Welding

In this process, an electric arc between the two faces of the workpieces to be butt welded produces the heat required to melt the faces, and the workpieces are then pressed together. This squeezes out the slag which forms in the gap, so

that a good metallic joint is formed. The compressive force produces a welding burr which must be machined off in the case of larger components.

In arc flash-butt welding, considerably larger sections identical to each other are joined together by large machines using a basically similar process, but with a longer operating cycle.

In stud welding, studs are individually welded onto one side of large surfaces using manual equipment. This process is used especially in the construction of heat exchangers to increase the area of the heat transfer surface.

3.2.3. Induction Welding

Induction welding (Fig. 24) is a type of pressure welding in which the heat is provided by electrical induction. It is mainly used in the production of tubes by longitudinal welding.

Figure 24. Principle of induction welding of a tube
a) Workpiece being welded to form a tube; b) Induction heating coil; c) Feed and compression rollers; d) Pressure welding point

Friction Welding. In friction welding, the heat for the welding process is generated by rubbing the workpieces together at high speed. For example, the end faces of two shafts can be rubbed together until softening (at least) occurs, after which the rubbing operation is stopped and the two shafts are pressed together. The pressure/force program must be very precisely matched to the friction program.

Gas Pressure Welding. In gas pressure welding, the components are heated with gas flames to the fusion temperature and then pressed together. The process is mainly used for welding small tubes. The equipment required is usually simple.

3.3. Special Welding Processes

Some welding processes cannot be classified as either fusion or pressure welding (see Fig. 2 B), e.g. diffusion welding.

Diffusion welding is an important special welding process in which the joining surfaces of the two workpieces, which fit together exactly, are very carefully smoothed and then heated to the diffusion temperature in a high vacuum while pressing them together with only a small force. The diffusion temperature (in °C) is ca. 2/3 of the fusion temperature. The process is very expensive owing to the careful surface preparation required and the high-vacuum technology. It has so far been little used, and only for very high value materials, but produces an ideally welded joint.

4. Fusion Cutting Processes

4.1. Flame Cutting (Autogenic Cutting)

In flame cutting, the surface of the workpiece is heated by the fuel gas – oxygen flame of the cutting torch at least to the temperature at which scale forms. Part of the cutting oxygen then oxidizes part of the metal, and the very strongly exothermic combustion reaction provides the heat to melt the adjacent metal. The molten material, which consists of oxides and unoxidized metal, is blown out of the gap by the remainder of the cutting oxygen.

The process of flame cutting is therefore governed by two preconditions:

1) The scaling temperature of the material to be cut must be lower than its fusion temperature
2) The oxides formed must not form a continuous skin, so that the oxygen can penetrate to the surface of the melt

The most important part of the cutting torch is the nozzle (Fig. 25) which shapes the jet of cutting oxygen, the actual cutting tool in this process. The exit openings for the flames are usually

rotationally symmetrical about the cutting oxygen jet, so that with the jet directed vertically downward it can cut in all horizontal directions.

Figure 25. Mechanical cutting torch

In very thick walled workpieces, the flames also heat the side walls of the gap produced in the direction of cutting immediately behind the cutting oxygen jet. The viscosity of the molten material produced then remains low and it can be blown out of the gap almost completely. Slower burning gases such as propane are better than acetylene for achieving this result.

All the plain carbon and low-alloy steels with a wide range of thicknesses (3 mm to >2 m) can readily be flame cut by this method, but not chromium steels (see below). The maximum cutting speed depends not only on the properties of the cutting oxygen jet, but also very much on the thickness of the workpiece (Fig. 26). The required quality of the cut can limit the cutting speed. Faster cutting speeds can be used if the quality of cut need not be high.

Figure 26. Speed of flame cutting plain carbon steel with a high-power nozzle as a function of workpiece thickness
a) Results achievable with optimum quality cut; b) Results if there is no quality requirement

Chromium steels cannot be flame cut conventionally, as the chromium in the steel increases the solidification temperature of the oxide melt, and an oxide skin forms. This chromium oxide skin disappears if iron powder is injected at an angle from the sides through the flame and into the oxygen jet. The iron then burns on the molten material and provides more heat. This trick enables chromium steels to be flame cut.

The range of flame cutting equipment extends from simple hand torches and portable flame cutting machines to large stationary machines. There are many ways of controlling these machines, including photoelectric scanning of a pattern (which may be a line drawing) and control by mainframe computer.

4.2. Plasma Cutting

Plasma cutting continues to grow in importance. All the electrical energy required is supplied externally, so that, unlike the flame cutting process, this process generates no additional heat. The design of the plasma cutting burner (Fig. 27) is almost identical to that of the plasma welding burner (see Fig. 6), except that there is no gas shield. Also, the power outputs of plasma cutting equipment (up to ca. 50 kW) are higher than those of welding equipment, enabling 100-mm thick steel to be cut.

Figure 27. Principle of plasma cutting
a) Tungsten cathode; b) Copper nozzle; c) Plasma jet; d) Workpiece

Plasma cutting can be used with all electrically conducting materials. Cutting rates for thin sections are higher than with flame cut-

ting. A mixture of argon and hydrogen has been found to be a suitable plasma gas for cutting austenitic chromium – nickel steels and aluminum. For high-carbon structural steels, for which high cutting speeds are an advantage, the plasma gases used are air or other nitrogen-containing mixtures. With air as the plasma gas, a water-cooled copper electrode fitted with a small lanthanum plate insert is used instead of the usual pointed tungsten electrode.

An alternative process, the water plasma process, can also be used for cutting structural steels. Water is radially injected into the cutting nozzle immediately behind the narrowest cross section of the jet. This prevents burr formation when cutting plain carbon steel (Figs. 28).

Figure 28. Principle of water plasma cutting
a) Tungsten cathode; b) Copper nozzle; c) Plasma jet; d) Ceramic nozzle; e) Workpiece

In all the plasma cutting processes described above, the noise level is high, and harmful substances are emitted. In stationary plasma cutting equipment, these substances are usually removed by air extraction. Noise levels can be much reduced by surrounding the plasma jet with a shielding envelope of water or by carrying out the process under water.

4.3. Laser Cutting

The laser beam can be focused by relatively simple optical means to give an extremely small spot (with an effective beam diameter of ca. 10^{-1} mm). Part of the material from the gap is evaporated, and the fused material formed is blown out by a coaxial gas stream. If the latter consists of oxygen, the cutting effect is considerably improved. The gap produced is narrow and smooth, and the heat-affected zone is small. Power outputs of metal-cutting lasers are in the range 500 – 3000 W. High-pressure nitrogen has been found suitable for cutting stainless steels (see Fig. 21).

Solid-state lasers with power outputs of up to 1 kW are available. Solid state lasers combined with light guides have proved to be very useful for metal cutting by robots operating in poorly accessible locations.

5. Welding of Various Materials

It was shown in Section 2.3 that the welding behavior of a metallic construction material is mainly determined by its chemical composition, and that each alloy type has its own special characteristics.

5.1. Plain Carbon Steels

The compositions, mechanical properties, and commercially available qualities of plain carbon steels (→ Steel, Chap. 6.1.1.4., → Steel) are listed in EN 10 025 : 01.91 (general structural steels). Their welding properties are determined by several factors: carbon content (small additions of silicon and manganese have a small effect), degree of deoxidation (killed or rimming steel, → Steel, Chap. 3.4.1.1., → Steel, → Steel), and the level of impurities (sulfur, phosphorus, arsenic, copper, etc.). Other important factors include the smelting process [Siemens – Martin or open-hearth process, oxygen blast process (LD process), electric furnace process], the casting process (Shell casting, continuous strand casting), and the delivered state (normalized, cold-hardened).

Plain carbon steels with carbon content up to ca. 0.25 % and an impurity level corresponding to the state of the art can be welded without problems, especially if they are fully killed, so that they do not completely lose their grain fineness on welding.

Steels with a high carbon content can also be welded if hardening is prevented by welding

when hot and following this with an additional heat treatment.

5.2. Alloy Steels

Most so-called low-alloy steels, i.e., those containing a total of up to 10 % alloying elements (→ Steel, Chap. 6.2.1.2.), can be welded like plain carbon steels. However, there is a limit to the acceptable carbon content, owing to its hardening effect, and the other alloying elements also affect the welding properties from the point of view of through tempering. This means that, with increasing levels of alloying elements, the size of the section to be welded is also important.

Whereas in plain carbon steels the type of filler metal depends mainly on the properties required (strength, toughness, gap-filling property, high yield), in alloy steels, the chemical composition must also be considered. Further details on steels and the appropriate filler metals are available in steel manufacturers' recommendations.

The important alloying elements in low-alloy steels include chromium, nickel, molybdenum, vanadium, tungsten, copper, and nitrogen. The family of low-alloy steels includes tempering steels, low-temperature steels, high-temperature structural steels, and high-strength structural steels. Further details can be found in EN 10 083, Parts 1 and 2 (tempering steels).

The high-alloy steels, in which the total content of alloying elements exceeds 10 %, require special care in welding. These steels include:

1) Low-temperature steels with 9 % nickel
2) Corrosion-resistant ferritic chromium steels containing at least 12 % chromium
3) Corrosion-resistant austenitic chromium–nickel steels containing at least 17 % chromium and 8 % nickel [31]
4) The high-temperature and very high temperature steels based on 16 % chromium and 13 % nickel

It is possible to use 9 % nickel steel at liquid nitrogen temperature (−196 °C) for components in the cryogenics industries. It cannot be welded with filler metal of the same composition for strength reasons, but must be welded either with a nickel-based alloy, or, for increased strength, with a filler metal containing chromium, nickel, and tungsten as alloy components.

The corrosion-resistant ferritic chromium steels are generally difficult to weld. The main reasons for this are the very considerable grain growth that occurs during welding and the consequent loss of toughness and increased incidence of intergranular corrosion problems (→ Corrosion, Chap. 3.2.3.1.). In spite of these difficulties, these steels are weldable if certain precautions are taken.

The corrosion-resistant austenitic chromium–nickel steels have become extremely important in the construction of chemical plant. Because they do not undergo transformations, they have good welding properties in all welding processes if their individual characteristics are borne in mind. Intercrystalline corrosion is minimized by suitable choice of the alloy composition. For example, steels with a low carbon content can be used, or those in which the carbon is chemically combined with niobium or titanium. The required degree of stabilization of this type depends on the time during which the metal is within the main precipitation temperature range (550–800 °C).

The high-temperature and very high temperature 16 : 13 chromium–nickel steels have very similar welding properties to those of the austenitic chromium–nickel steels. If it is intended to heat treat these metals before use by solution annealing and hardening, they are welded in the solution-annealed state and hardened after welding.

The corrosion-resistant austenitic–ferritic steels are seldom used, but are valuable because of their resistance to wear and corrosion. However, their precipitation behavior leads to welding problems. The ferritic steels are superior from the point of view of grain growth. However, such welding operations should be limited to the smallest possible areas.

If metals of different structure types are welded together, e.g., austenites to ferrites (black-to-white joint), the Schaeffler diagram provides useful information on the resulting metal structure [1, p. 128], [32]. In this diagram, the ferrite-forming and austenite-forming elements are summarily represented (including a weighting factor) in such a way that the phase field of the probable structure types can be estimated. Each steel alloy is represented by a particular point in the diagram. If the points for the

two different metals to be welded are joined together, the expected mixing ratio of the mixed structure lies on this line.

5.3. Cast Steel

Like rolled steel, normal cast steel can be welded using filler metal of the same type and composition. With large sections and cast steel components of complex design, it is necessary to look out for the possible presence of interior stresses. These are much more likely to be detected by experienced than inexperienced welders.

5.4. Cast Iron

All three types of cast iron, i.e., malleable iron, gray iron (with lamellar graphite), and SG iron (with spheroidal graphite), can be welded, with the exception of blackheart malleable iron (not decarburized by heat treatment). Whiteheart malleable iron (decarburized by heat treatment) can be welded without problems at its decarburized edge zone to produce structural welds. The structure of the edge zone corresponds to that of low-carbon steel.

Gray iron can be welded for repair purposes by two methods. In welding with preheating, the casting is heated to ca. 650 °C, welded at this temperature with filler metal of the same composition, and then cooled very slowly to prevent cracking. The low-viscosity weld metal is prevented from running off by fitting shaped carbon plates around the welding area. The solid weld metal is of identical quality to that of the parent metal. Welding of gray iron with filler metal of the same type without preheating is impossible. Instead, pure nickel and nickel – iron alloys are used because their thermal expansion coefficients are similar and they have very good ductility. In the welding process, the parent metal near the welding zone must be only slightly heated. Therefore, in manual arc welding, thin electrodes are welded on as short seams in various places. These seams are spread out in longitudinal and transverse directions by hammering during cooling to minimize the interior stresses. The joint produced by welding gray iron without preheating is not of such high quality as that obtained by welding with preheating.

Cast iron containing spheroidal graphite (SG iron), unlike gray iron, has generally good ductility, the breaking elongation being controllable by varying the composition. The weld metal and the parent metal should have approximately similar elongation properties. By using nickel – iron alloys as filler metal, the weld produced is always ductile. By using weld metal identical to the parent metal, the elongation properties of the weld metal can be exactly matched to those of the parent metal. When welding without preheating, the hardening effect produced must be counteracted by subsequent heat treatment [1]. Welding of cast iron and SG iron is not only used for repair purposes, but sometimes also as a fabrication method.

5.5. Nickel and its Alloys

Nickel and nickel alloys are characterized not only by their good physical properties (strength and toughness), but also by their excellent corrosion resistance. Additions of chromium, molybdenum, and various other alloying elements further improve the hot strength. These properties have led to the widespread use of nickel and nickel alloys in the construction of chemical equipment. Pure nickel [33] and the following groups of nickel alloys are particularly important: nickel – copper (monel), nickel – chromium – iron (Inconel), nickel – chromium – molybdenum (Hastelloy), and the hardenable chromium-containing nickel-based alloys based on Ni_3TiAl, the so-called Nimonic alloys, for very high hot strength.

Nickel can be welded by all the welding processes. For the most important alloys, especially the high-temperature alloys, identical filler metals are available both for manual arc welding and for welding processes with shielding gases. For welding tube joints in reactor construction, in gas turbines, and in chemical equipment construction, most processes are fully automated, in particular electron beam welding.

Because of its physical properties, especially its poor thermal conductivity, the weld preparation, the welding electrodes, and the protective gas selected must enable long periods of degassing time to be available during the solidification process. Small-section electrodes with small current consumptions are usually used to

minimize the amount of heat applied, and the protective gas should have a low thermal conductivity (e.g., argon).

For good weld quality, it is important that the workpieces and filler metals should be free from oil, dirt, oxides, and sulfides; nickel has an extremely strong affinity for sulfur, so a low-melting nickel sulfide (637 °C) can form in the weld seam and lead to cracks in the joints, even if the quantity is extremely small. The solubility of sulfur in nickel is <0.005 %. Nickel can take up trace amounts of sulfur from substances in the form of gases or vapors or from greases and lubricants, even after extremely small exposure times. Carbon can lead to graphite precipitation at grain boundaries, so the level of this element must be limited if niobium or titanium has not been included in the alloy to give carbide formation (Inconel alloy).

Unlike steel, nickel and its alloys are not very sensitive to hydrogen. As nickel is expensive, it is often used only as a plating or cladding material in chemical equipment. The welding of plated components requires great care to prevent the parent metal from mixing with the plating layer.

5.6. Copper and its Alloys

One of the most important properties of copper, its very good electrical and thermal conductivity, has a decisive influence on its welding properties. There must be a very plentiful heat supply for the welding process. If this is allowed for, copper can be welded by all the welding processes. Autogenic welding is still often used with copper, mainly for welding tubes; a flux is usually used (see [1, p. 167], EN 29454-1: 1994, and ISO 9454-1: 1990). Thorough preheating is important for producing a penetrating weld.

A condition for good weldability of copper and its alloys is low oxygen content, as copper and oxygen react to form a copper/copper(I) oxide eutectic which precipitates at the grain boundaries on solidification of the melt and causes embrittlement.

Copper – zinc alloys (brass) are usually soldered, not welded. This is also true of special brasses with high strength and corrosion resistance.

Copper – tin alloys (tin bronzes) have extremely good corrosion resistance and are much used in freshwater treatment plants containing highly chlorinated solutions. In spite of their susceptibility to hot cracking, these alloys can be welded with manual electrodes and also by the TIG process. They are also used in the production of armor plating by the explosive method.

Copper – aluminum alloys can also be welded by all the electrical welding processes, but the aluminum oxide layer adheres very strongly and causes welding difficulties (see Section 5.7).

5.7. Aluminum and its Alloys

Aluminum and its alloys are increasingly used in the construction of chemical equipment, especially for moving parts for which low density is an advantage. These materials have good corrosion resistance, and their low-temperature toughness properties enable them to be used at liquid nitrogen temperature.

The main problem in welding is dealing with the film of aluminum oxide scale which adheres extremely strongly and has a very high melting point. As the thermal conductivity of aluminum metal is also very high, there must be an ample heat supply so the weld pool does not solidify too rapidly or contain nonmetallic particles or gas-filled pores.

The simplest process, welding with manual electrodes, is widely used and is completely satisfactory for simple joints. Qualitatively good welds can be produced by the TIG and MIG processes. The preferred protective gas is helium. The alternating current removes the layer of aluminum oxide. If the weld is carefully prepared and the auxiliary materials have been correctly chosen (surface cleanliness), mechanically sound low-porosity welded joints are obtained. High-power processes such as submerged arc welding are also suitable.

Owing to the low melting point of aluminum, the low viscosity of the molten metal, and the small difference in density between the metal and its oxide, manual welding of aluminum and its alloys makes extremely high technical demands on the welder.

5.8. Titanium and its Alloys

The physical properties and corrosion resistance of titanium and its alloys have aroused interest in its use in the chemical industry as well as aircraft construction. As is the case with steel, the main welding problem is its reactivity with oxygen, nitrogen, hydrogen, and carbon, so electron beam welding in vacuum is very useful for titanium, although titanium and its alloys can also be welded by the TIG and MIG processes if suitable precautions are taken.

As even the small amount of gas uptake that occurs at slightly elevated temperatures leads to embrittlement, the weld zone must be very rapidly cooled. The heat supplied can be rapidly removed by welding on a copper base, and by using cooling sprays in the region of the heataffected zone. Essential preconditions include an absolutely clean welding surface, oxide-free filler metals, and pure protective gases. The gas nozzles used are specially designed to retain the protective gas for as long as possible at the weld as it cools and in the region of the heat-affected zone. If these precautions are taken, physically sound joints can be produced.

5.9. Thermoplastic Materials

Of all the various types of plastic materials, only some thermoplastics are weldable [34]. No thermosetting materials can be welded. The weldable thermoplastics include polyethylene, polypropylene, poly(vinyl chloride), poly(methyl methacrylate), and polyisobutylene. Polytetrafluoroethylene and polytrifluorochloroethylene are not weldable.

In all welding processes for plastics (see also → Plastics, Processing, Chap. 3.2.1.), the material is softened by supplying heat to the surfaces to be welded. This heat is usually provided by a current of hot gas (air, nitrogen) or by applying heatable metal plates (heating elements or heat reflectors). Other techniques include the application of wires through which an electric current is passed, heat pulses, friction, high-frequency heating, and ultrasound. The workpieces are then pressed together at the weld surfaces, or softened filler material is pressed into the surfaces to be welded.

The welding of thermoplastic materials is used mainly in the construction of pipework (Fig. 29), equipment, machinery, and packing materials. The conditions for a good welded joint include similarity of the types of materials to be welded, a design suitable for the service requirements, choice of the most suitable welding method, and cleanliness of the parts to be joined.

6. Testing and Control Methods

In principle, the testing methods used in welding technology are the same as those used in general materials testing. However, there are additional procedures designed specifically for testing welded joints and the weldability of materials.

The following standards are for destructive testing:

DIN 50 120 Parts 1 and 2: Tensile testing of welded joints; also ISO 4136: 1989
DIN 50 121 Parts 1 – 3: Technical testing of transverse properties of welded joints; also ISO 5173: 1981; ISO 5177: 1981; ISO/DiS 5173: 1992
DIN 50 122: Notched-bar impact testing of welded joints; also ISO/DiS 9016: 1992
DIN 50 124: Testing of shear strength of spot welded joints; also ISO 10 447: 1991
DIN 50 127: Notch-tensile strength
DIN 50 129: Cracking tendency of filler materials

The following standards are for nondestructive testing:

DIN 54 109: Picture quality in radiographic testing
DIN 54 111: Testing with X-rays and γ-rays; also ISO 1027 : 1983; ISO 1106-1/3

The most important nondestructive testing methods are radiography with X-rays and γ-rays (→ Nondestructive Testing, Chap. 2.2.) and ultrasonic testing (→ Nondestructive Testing, Chap. 2.3.). Ultrasonic testing is comparatively difficult and still in the development stage. Interpretation of the ultrasonic pictures is difficult, for example, differences in grain size may not be shown or may be interpreted as defects. Current developments in computer-controlled ultrasonic testing methods should lead to improvements in picture interpretation.

Figure 29. Welding of polyethylene pipe

There are considerable developments in control systems that continuously monitor the welding process by detecting deviations of welding parameters from standard tolerance ranges and draw conclusions concerning the quality of the weld. There are already many successful applications of these methods in spot welding, but they are in an early stage of development for arc welding. For the methods to be successful, it is necessary to know the tolerance limits within which the fluctuations of the process parameters do not cause any harmful effect on the weld. Manufacturers of welding equipment are working hard on this problem, and progress is expected in the near future.

7. Health Protection and Safety

7.1. Health Protection

Incorrect operation of a welding process can lead to hazards to personnel, especially from electric current, explosive gases, atmospheric pollutants (smoke, vapors, and gases), radiation, and noise [37].

To minimize the hazard from electric current, machines should conform to the relevant safety guidelines, e.g., in Germany, those of the VDE. The special hazards associated with restricted working areas are reduced, for example, by limiting the no-load voltage to 42 V. If higher no-load voltages are necessary for technical reasons, e.g., for plasma cutting, the potential hazard is minimized by the use of suitable protective circuits.

Strong light can be emitted by electric arcs, plasma jets, direct and reflected laser beams, and bright flames. These are mainly hazardous to the eyes and the exposed skin. The eyes should be protected by filters (see DIN EN 167, ISO 4849, DIN EN 169, and ISO 4850: welding protection filters, DIN 58 211, Part 6: safety spectacles, DIN 58 125: optical protection filters against laser light), and the skin is protected by suitable covering (textiles and leather).

The concentrations of atmospheric pollutants such as airborne particulates (fume), vapors, and gases must not exceed the legal limits, i.e., the MAK values [36]. The airborne particulates contain lead, chromium, cadmium, nickel, mercury, copper, and zinc. They are formed as metal vapor during the processes of welding and soldering, and usually become oxidized and suspended in the air as fine dust. Fume formation can be excessive, especially when welding with coated electrodes. The harmful gases formed can include nitrogen oxides (NO, NO_2) from flames, ozone and sometimes phosgene from the intense light emitted by electric arcs, and carbon monoxide when welding with a carbon dioxide gas shield. Protection from harmful vapors and gases must be provided, especially when working in confined spaces, e.g., air extraction plant and equip-

ment for supplying clean air [37]. The use of pure oxygen is prohibited because of the danger of fire and explosion.

Noise can be produced by the high-velocity gas jets and flames used in welding and cutting technology, e.g., those used in cutting torches and plasma equipment. Effective countermeasures include simple sound-absorbing shields, which absorb the high-intensity, high-frequency components.

7.2. Safety

When welding and cutting, it is extremely important to take precautions against fire, which can be produced directly by flames, or can begin slowly due to unnoticed molten material impelled over long distances, often only becoming serious after some hours.

Fuel gases constitute a further source of danger (e.g., acetylene, propane, etc.). Acetylene has a wide range of explosive concentrations and requires special safety precautions (→ Acetylene, Chap. 5.). Propane is considerably denser than air, and, after escaping from leaks in equipment, can collect in hollows or spread out for long distances over a level floor, and can then be accidentally ignited far from the leak source.

When working with oxygen, it is essential that the surfaces of the equipment with which it comes into contact (especially manometers, valves, tubes, and hoses) are free from oil and grease in order to prevent spontaneous ignition.

Accident prevention guidelines must be observed [37].

8. Economic Importance

Welding is a basic operation in the fabrication of equipment and machinery from individual components. Although the autogenic technique is still important, most welding operations are now carried out by gas-shielded processes. The growth of computer methods for the control and regulation of processes and the establishment of data banks and expert systems is typical of the progress being made in solving welding problems. Modern computer technology is used not only for controlling the process of welding, but also for establishing weld geometry and for controlling the burners.

Manual electrodes constitute an important part of welding technology, as they can readily be modified by changing the coating or the cored wire to suit the composition of a new material.

Beam welding methods are now of great economic importance. The increased speed of this welding process gives not only improved economics, but also a reduction in the extent of the heat-affected zone, and therefore continuing improvement of the conservation of the quality of the material in the region of the welding or cutting zone.

The spot welding technique occupies a special position. Its effect on added value is very significant, e.g., in automobile construction. Economic comparison with the other welding processes is not easy. The development of spot welding technology is also dominated by electronics.

Developments in the technology of cutting go hand-in-hand with those in welding. Although autogenic cutting is still the most widely used process, beam methods show the greatest growth rate. Three-dimensional cutting with high-power lasers is already an important feature of modern fabrication processes.

1. Introduction and Historical Development

Whiskers are filamentary single crystals with an aspect ratio (i.e., length-to-diameter ratio) of usually over 10 and a diameter in the range of 0.01 – 10 µm [1]. Such crystal shapes have a very large surface area to volume ratio. The high degree of chemical purity and structural perfection of whiskers, which is due to their single-crystal morphology and small diameter, make them the strongest form of materials. The strength of some whiskers approaches the theoretical strength of the material predicted by OROWAN:

$$\sigma_{\text{theo}} = (E\gamma)^{1/2}/a$$

where E is the Young's modulus, γ is the surface energy per unit area, and a is the equilibrium spacing of the atomic planes. The absence of grain boundaries and line defects in whiskers also ensures better creep resistance and, therefore, higher temperature capability compared to polycrystalline fibers or bulk materials.

Being single crystals, most whiskers have a noncircular cross-section. The shape of the cross-section depends on the crystal structure and the growth orientation of the whisker. Thus, it can be triangular, hexagonal, rhombohedral, or another shape. For a noncircular cross-section, whisker diameter is defined as the square root of the cross-sectional surface area. The shape of the whisker affects the total whisker – matrix interfacial area for whiskers used as reinforcements, conducting fillers, etc. in ceramics, metals, or polymeric materials. The interface in turn has a strong influence on the physical and mechanical properties of the composites.

The existence of crystal whiskers has been known for centuries. In his *Treatise on Ores and Assaying*, published in 1574, ERCKER discusses the natural and artificial occurrence of silver whiskers, known as hair silver. However, the importance of whiskers as a form of materials with unique properties was recognized in 1952 when HERRING and GALT at Bell Laboratories discovered that whiskers have mechanical properties close to those of dislocation-free crystals [2]. A rush of activities then followed in the growth, modeling, and property characterization of whiskers. In 1958, The Air Force Office of Scientific Research, Air Research and Development Command, and the General Electric Research Laboratory sponsored an international conference on crystal growth, of which two major sessions were dedicated to whiskers [3]. In a comprehensive review presented at that conference, NABARRO and JACKSON have documented the history of natural and synthetic whiskers and the state of science, up to that point, of whisker growth from vapor, melt and solution, by chemical decomposition, by electrolysis, and under mechanical stress [4]. The majority of whiskers grown then were whiskers of metals, including tin, zinc, cadmium, copper, and iron [5–7].

Early investigations of whiskers primarily focused on dislocation structures and their role in the mechanical properties, although some studies of the ferromagnetism in iron whiskers were also conducted [8,9]. Also at that same conference, Brenner gave an extensive review of the mechanical properties of whiskers, including whiskers of tin grown from solid; whiskers of zinc, cadmium, silicon, and mercury obtained from vapor; whiskers of iron, copper, nickel, cobalt, and silver grown from the reaction of metal halides; and whiskers of sodium chloride and potassium chloride prepared by precipitation from solution [10]. An example of the stress – strain curves for iron and copper whiskers are shown in Figure 1. Figure 1 illustrates a large deviation from linearity in the elastic behavior of iron whiskers, which show an elastic strain close to 5 %. Similar deviations from Hooke's law have also been observed in whiskers of zinc and some other metals, but not in copper [11].

Figure 1. Stress – strain curves of iron and copper whiskers pulled in tension [10]

With the advent of metal- and ceramic-matrix composites, a new wave of activity began in the 1980s towards the development of ceramic whiskers as reinforcements for metals, ceramics, and some polymers. A fair amount of research has been also going on in the area of whiskers of conducting, semiconducting, and superconducting materials.

This article provides an overview of the present day whiskers with actual or potential use in thermal, mechanical, and electronics applications. Effort is made to cover not only whiskers that are commercially available but also those that are still in early stages of investigation and development.

2. Applications and Commercial Products

Asbestos whiskers and fibers have traditionally been used for thermal insulation in buildings as well as for heat-shield applications. The discovery of the health hazards of asbestos, however, has led to a severe limitation and regulation of asbestos use in the construction industry. At present, the most active area of whisker development is for reinforcement applications in metal- and ceramic-matrix composites. The bulk of the work in whisker-reinforced metal-matrix composites has been with aluminum matrices [12,13]. In ceramic-matrix composites, in addition to alumina [14,15], which constitutes the major matrix material investigated, other matrices such as boron nitride [16] and zirconia [17] have also been considered. Although whiskers are usually quite short, they possess large aspect ratios, usually over 20, due to their small diameters and are thus efficient reinforcements. Whisker diameter is also a critical parameter in terms of strength; increasing the diameter raises the probability of the presence of defects, hence lowering the strength.

Whiskers are incorporated in metals to increase the stiffness, creep resistance and wear resistance of the matrix, while in ceramics their role is to increase toughness, creep resistance, and wear resistance. Toughness enhancement in whisker-reinforced ceramic-matrix composites occurs through a variety of mechanisms, which include crack deflection [18,19], crack bridging [20], and whisker pullout [21,22]. Three- to fourfold increases in the toughness of alumina have been reported on incorporation of SiC whiskers [14,23]. Figure 2 illustrates a SiC whisker pulled out in SiC(w)/Al_2O_3 composite. Whiskers are used both as the sole reinforce-

ment and in combination with fibers to provide added toughness. Whisker-reinforced ceramics are used in cutting tools and considered as high-temperature materials for engine components.

Figure 2. Whisker pullout in the SiC(w)/Al_2O_3 ceramic composite systems

The potential use of whiskers as conducting, semiconducting, or superconducting fillers for some polymers has also been recognized and is under investigation.

The range of whiskers commercially available is still quite limited. Table 1 summarizes some commercially available reinforcing ceramic whiskers. In most cases, whisker prices are very high, at least several hundred dollars per pound, because of the small production volume and/or the processing route. The high cost of whiskers is still a major barrier to their widespread use in composites. Among the commercially available whisker reinforcements for composites aluminum borate is one of the cheapest.

3. Asbestos Whiskers for Thermal Resistance/Insulation Applications

Asbestos (→ Asbestos) is a general name for a variety of fibrous minerals known as amphiboles, which are hydrated silicates containing chiefly Mg, Na, Fe, and Al. The majority of commercial asbestos whiskers or fibers come from the mineral chrysotile [$Mg_6Si_4O_{11}(OH)_6 \cdot H_2O$] but other minerals, including actinolite [$CaMg_nFe_{3-n}(SiO_3)_4$], tremolite [$Ca_2Mg_5H_2(SiO_3)_8$], crocidolite [$NaFe(SiO_3)_2$], and anthophyllite [(MgFe)-SiO_3] are also important sources [24].

The size and morphology of asbestos filaments are as broad as their compositions. Filament size can range from <1 µm to >2 mm in diameter, and from a few micrometers to nearly 100 mm in length. From their structures, asbestos filaments may or may not be considered as genuine whiskers. Some fibrous silicates, such as actinolite and tremolite, have chain structures based on the amphibole (SiO_3) chain [25]. Chrysotile fibers, however, are hollow tubes, as shown in Figure 3 [26, 27]. A structural model has been proposed for chrysotile asbestos which consists of alternating silicon – oxygen layers in tetrahedral coordination and magnesium – hydroxyl layers in octahedral coordination [28]. Each silicon – oxygen layer is strongly bonded to a magnesium-hydroxyl layer, forming a double layer. The double layers, however, are weakly bonded together. Because the alternate tetrahedral and octahedral layers have different lattice parameters, the layered structure curls, forming a hollow scroll that looks like a whisker or fiber.

Long asbestos fibers are woven into fabrics and used in brake linings, fire-proof articles, curtains, heat shields, etc. Because of the high chemical resistance of asbestos, asbestos fabrics have also been used as acid filter cloths. Short fibers have been traditionally mixed with a binder and made into insulating boards, paper, shingles, piping blankets, etc. However, since the discovery of asbestosis, a form of lung cancer caused by the inhalation of asbestos dust, the use of asbestos in construction has been severely curtailed and regulated.

Asbestos fibers have tensile strengths ranging from 0.5 GPa to over 4 GPa and a melting point above 1480 °C. Above 980 °C, the hydrous silicate loses its water, thus producing a cooling effect.

Because of the health hazards of micron-size asbestos fibers, a large effort was launched in the 1970s towards the development of larger-diameter refractory fibers. This led to the de-

Table 1. Selected whiskers and their properties

Material	Designation	Phase	Manuf.	Diameter, µm	Density, g/cm^3	Coefficient of thermal expansion, K^{-1}	Young's modulus, GPa	Tensile strength, GPa	Length, mm

velopment of alumina fibers and staples. Since the primary application of alumina and mullite whiskers and fibers is as reinforcements, they are discussed in Chapter 4.

4. Whiskers for Reinforcement Applications

4.1. Silicon Carbide Whiskers

General Characteristics and Uses. SiC whiskers are presently the most widely used whisker reinforcements for ceramic-matrix composites [15, 29] as well as metal-matrix, particularly aluminum [12, 30, 31], composites.

Silicon carbide has two polymorphs: α-SiC with a wurtzite hexagonal or a rhombohedral structure and β-SiC with a zinc blende cubic structure. A wide variety of SiC polytypes have been reported [32]. These polytypes are usually described using Ramsdell notation [33]. The Ramsdell notation (e.g., 2 H, 1200 R, 3 C, etc.) consists of a number, representing the number of silicon and carbon double layers in the unit cell, followed by a letter identifying the Bravais lattice type (C for cubic, H for hexagonal, R for rhombohedral).

The majority of commercially available SiC whiskers are of β type grown in the $\langle 111 \rangle$ direction, although some have α or a mixture of α and β structures. The β-SiC whiskers usually have mechanical properties superior to those of α-SiC whiskers, probably due to their smaller defect density and better consistency. The physical appearance (e.g., shape, size, and color) and structural characteristics of these whiskers are highly dependent on the manufacturing process. β-SiC whiskers from various manufacturers, even when produced by basically the same processing route, show colors ranging from white to light-brown to dark-green, and aspect ratios in the range of 1 – 100 µm [1]. Such variations, in turn, result in a broad range of the mechanical properties. Table 1 includes SiC whiskers from a variety of manufacturers, along with some of their physical characteristics and properties.

Production. There are several mechanisms for SiC crystal growth. One method is the vapor-solid (VS) mechanism [34]. β-SiC whiskers have been grown using chemical vapor deposition of β-silicon carbide onto a carbon substrate by hydrogen reduction of methyltrichlorosilane gas at 1500 °C [35]. At present, however, the most commonly applied methods of production are the carbothermal reduction of silica [36] and the vapor – liquid – solid (VLS) process [37, 38].

The majority of commercial SiC whiskers are obtained by the carbothermal reduction of silica. The overall carbothermal reaction is written as [39]:

$$SiO_2(s) + 3\,C(s) \rightarrow SiC(s) + 2\,CO(g) \quad (1)$$

Below 1400 °C most of the SiC is produced by reaction (1). At higher temperatures, however, the solid-state reaction is replaced by the gas – solid reactions:

$$SiO_2(s) + CO(g) \rightarrow SiO(g) + CO_2(g) \quad (2)$$

$$SiO(g) + 2\,C(s) \rightarrow SiC(s) + CO(g) \quad (3)$$

$$2\,SiO(g) \rightarrow Si(s) + SiO_2(g) \quad (4)$$

Other possible reactions for SiC whisker formation are [36,40]:

$$SiO(g) + 3\,CO(g) \rightarrow SiC(s) + 2\,CO_2(g) \quad (5)$$

and [41]:

$$3\,SiO(g) + CO(g) \rightarrow SiC(s) + 2\,SiO_2(s) \quad (6)$$

The most economic and widely used production method based on carbothermal reduction of silica is the pyrolysis of silica and carbon obtained from rice hulls [41–45]. The Silar SC-9 whiskers (Table 1) are manufactured in this way. Rice hulls contain ca. 15 – 20 % silica and are a cheap and abundant source of silicon carbide whiskers. Sub-micron whiskers are produced by heating the rice hulls initially at 700 – 900 °C for 1 – 3 h in the absence of air or in an inert atmosphere, and subsequently above 1500 °C in a flowing inert or reducing atmosphere. The maximum yield of SiC is ca. 60 %, of which only 10 – 15 % is in the form of whiskers, while the remainder is SiC particulates [46]. Higher yields have been reported for the production of SiC whiskers by direct pyrolysis of rice hulls in a single-stage vacuum-pyrolysis process [44]. Four competitive processes have been identified during direct pyrolysis of rice hulls: (1) formation of SiC whiskers, (2) formation of SiC polycrystals, (3) crystallization of amorphous silica, and (4) formation of graphite from amorphous carbon [44]. More recently, Krishnarao et al. have reported on the formation of SiC whiskers from compacts of raw rice hulls without coking and catalyst [40]. Using a pyrolysis temperature of 1600 °C, they obtained α- and β-SiC whiskers, believed to have been formed by reaction of SiO(g) with CO(g).

Cerovic et al. (1995) investigated the effect of boric acid as a catalyst on the carbothermal reduction of silica [39]. They synthesized β-SiC whiskers by carbothermal reduction of silica, which was obtained from silica sol and saccharose in the presence of boric acid, in a carbon crucible. The presence of boric acid enhanced the crystallization of SiC into long, wide, regularly shaped whiskers. This was attributed to the formation of B_2O_3 which is thoroughly miscible in SiO_2 and provides for more intimate contact between SiO_2 and carbon.

In the VLS process particles of a catalyst metal are placed on a suitable substrate. The particles melt at the high temperatures of the reaction chamber. A mixture of gaseous C and Si compounds is then passed over the catalyst, whereby Si and C are extracted from the gases by the liquid catalyst. Crystalline SiC grows under the catalyst droplets, lifting the droplets off the surface of the substrate, once the liquid catalyst becomes supersaturated in C and Si. Figure 4 illustrates a schematic of the VLS process for SiC whisker growth. The VLS process has been adopted by Los Alamos National Laboratory and by Carborundum Company for the manufacture of β-SiC whiskers. A summary of advances made in the VLS process over the twenty five years of its development is given in [47].

Figure 4. Schematic of the VLS process for SiC whisker growth [72]

Bootsma et al. studied SiC whisker growth by the VLS method, using iron as the catalyst, and found that the growth rate was controlled by the rate of supply of the reaction feed gases [48]. They also observed that the SiC phases obtained depended on the substrate used. Milewski and co-workers [49,50] further investigated and optimized the process. They used stainless steel catalyst particles, a graphite substrate, and a mixture of SiO (generated by the reduction of SiO_2 with carbon), CH_4, H_2, CO, and N_2 gases. The CO gas was added in order to control the rate of production of SiO(g) from Reaction (1). SiC whiskers grew by the following reaction

$$CH_4(g) + SiO(g) \rightarrow SiC(s) + H_2O(g) + H_2(g) \quad (7)$$

It has been proposed that Reaction (3) may also take place, leading to SiC whisker formation [36].

It is observed that the iron droplets found at the tips of VLS-grown SiC whiskers are smaller than the original particles placed on the substrate, indicating that iron transport may have

taken place. URRETAVIZCAYA and PORTO LOPEZ investigated the mechanism of iron transport, using 20 – 30 µm Fe catalyst particles on a graphite substrate [51]. They also distributed small cubes, made of a mixture of silicon and carbon in isopropyl alcohol and serving as SiO generators, along the substrate surface. For comparison, in some tests separate cubes of pure SiO_2 and pure C were also distributed on the substrate alongside the SiO generator cubes. It was observed that extensive SiC whisker growth took place only when the Fe particles were placed at the upstream end of the substrate rather than being spread uniformly over it. Whiskers, carrying a droplet of catalyst notably smaller (2 – 3 µm) than the initial Fe particles at their growth end, grew in the high-temperature zone (1445 – 1475 °C) remote from the initial location of the particles. These observations clearly indicated that iron had been transported within the reaction chamber. The authors concluded that among the various possible transport mechanisms, vapor-phase transport was the only one likely to occur under the processing conditions. They further observed that the most extensive whisker growth happened on the surface of SiO generators where a high concentration of SiO existed. Whisker growth also took place, albeit to a smaller extent, on the surfaces of pure C cubes and the substrate but not on the pure SiO_2 surface, where carbon was not present.

Silicon carbide whiskers with much larger dimensions (diameter of 20 – 30 µm and lengths up to 2 mm) than those reported above have been grown from the vapor phase in the temperature range 2200 – 2600 °C [52]. These whiskers are reported to have a hexagonal shape and grow in the direction of heat flow.

Because of the difficulty in homogeneous mixing of whiskers with ceramic powders and the potential health hazards of handling small whiskers, several attempts have been made to form SiC whiskers in situ in a ceramic matrix. WANG and FISCHMAN prepared β-SiC whiskers in situ in a Si_3N_4 matrix by the reaction of silicon nitride with graphite in an argon atmosphere [53]. β-SiC formation began at 1400 – 1450 °C. The whiskers were needle-like with lengths and diameters depending on temperature. The product phases were dependent upon the Si_3N_4 : C ratio of the raw materials and the processing temperature. This "chemical mixing process" route was also followed by YAMADA et al. for in situ preparation of SiC(w) – Si_3N_4 composites [54]. JAGOTA and PARVIZI-MAJIDI used sol – gel processing to produce in situ composites of SiC whiskers in a mullite matrix [55]. This was achieved by mixing mullite precursor gel with carbon-doped silica gel and crystallization above 1400 °C.

Structure and Properties. As described above, SiC whiskers obtained from rice hulls are a mixture of α- and β-phases and are characterized by a hexagonal cross-section. The structural and chemical characteristics of Silar whiskers (Table 1) have been studied in detail [42, 56]. They contain a high density of planar faults lying on close-packed planes perpendicular to the whisker axis. The crystal structure of the whiskers ranged from faulted and twinned 3C polytype to thin lamellae of α and β polytypes normal to the whisker axis. Core regions of whiskers are often filled with small cavities ranging in size from 1 to 20 nm, accompanied by partial dislocations. Figure 5 shows the defect structure of a Silar SiC whisker. PICKARD et al. studied structural defects including twins, stacking faults, grain boundaries, and microvoids in β-SiC whiskers obtained from various manufacturers and found them to be highly dependent on the manufacturing process [1].

Figure 5. The defect structure of Silar SC-9 SiC whisker (a) perpendicular, and (b) parallel to the whisker axis [56]

Silicon carbide whiskers show excellent oxidation resistance in air up to at least 1000 °C. The thermal stability of Silar SC-9 whiskers un-

der oxidizing conditions has been studied [57]. Minimal oxidation occurred for whiskers heat treated for 5 h below 1000 °C. Heat treatment at 1000 °C for up to 96 h resulted in partial oxidation and formation of amorphous silica. Whiskers exhibited extensive oxidation after exposure at 1300 °C for 24 h, accompanied by the emergence of a nonstoichiometric crystalline silica phase. The same silica was observed at 1500 °C where whiskers were oxidized severely after only 1 h of exposure.

Whiskers grown by the VLS method consist almost completely of the cubic β-phase with their growth axis along the $\langle 111 \rangle$ direction. They have a rounded triangular cross-section with an effective diameter of 0.5 – 1.0 µm and lengths ranging from 1 mm to several centimeters. The VLS-grown SiC whiskers have a lower concentration of defects and therefore a higher strength and thermal conductivity than whiskers from rice hulls. These whiskers have been found to be remarkably uniform in size, a characteristic that has been attributed to the existence of a threshold catalyst droplet size for whisker growth [51]. The threshold size, however, depends on the substrate and the processing parameters used.

Petrovic et al. (1985) measured the tensile strength and Young's modulus of VLS-grown SiC whiskers by direct experiments and found quite a large scatter in both properties [58]. The strength decreased with increasing whisker length. Whiskers exhibited a considerable variation in their diameter, which contributed to the scatter in strength. The strength averaged at 8.40 GPa but reached as high a value as 23.74 GPa, which is almost half of the calculated theoretical strength of 46.3 GPa for SiC. The authors predicted a Young's modulus of 511 GPa for cubic SiC along the $\langle 111 \rangle$ direction. The experimentally determined modulus was about 15 % higher at an average value of 581 GPa.

Whisker surface chemistry and morphology affect the fabrication and properties of the resulting composites. Karasak and co-workers examined the chemistry and morphology of commercial SiC whiskers from various sources, using photoelectron spectroscopy (XPS) and scanning transmission electron microscopy (STEM) [59–61]. They found that all whiskers contained some carbon in their bulk composition. These investigators identified four categories of whisker surface chemistry:

1) A high-oxygen (>20 atom %) surface layer resembling SiO_2, prevalent in the earlier versions of whiskers when a HF acid wash was not employed to remove the silica surface layer
2) A low-oxygen (10 – 20 %) layer resembling Si – O – C glass (black glass)
3) A high-oxygen layer resembling Si – O – C glass
4) A predominantly hydrocarbon layer in those cases where a carbon layer had been deposited on the surface of the whiskers

All commercial SiC whiskers contain particulate matter, defined as particles of aspect ratio <5. Particle sizes typically range from submicron to >50 µm. Lee and Sheargold measured the particulate levels of SiC whiskers using an optical microscopy method coupled with wet sieve analysis [62]. They showed that the total particulate level ranged from 19 to 46 % among whiskers produced by different manufacturers. The authors further examined the effect of the particulate content on the flexural strength and fracture toughness of SiC(w) – borosilicate glass composites and concluded that particulate levels found in commercial whiskers did not significantly degrade the mechanical properties of the composite.

4.2. Silicon Nitride and Sialon Whiskers

General Characteristics and Uses. Silicon nitride whiskers, although still far less established than silicon carbide whiskers, have received increasing attention as reinforcements for composites because of silicon nitride's good high-temperature strength and thermal-shock resistance. Also, whisker – matrix compatibility is a major factor in the selection of the reinforcement for ceramic- and metal-matrix composites where the high temperatures encountered during processing or applications can lead to undesirable interfacial reactions. Therefore, for some matrices, Si_3N_4 whiskers may be a better choice than SiC whiskers. For example, Matsubara et al. have reported that Si_3N_4(w) – Al composites offer better tensile strength and machinability than SiC(w) – Al composites [63].

Silicon nitride (Si_3N_4) whiskers have two crystallographic modifications: α-Si_3N_4 with a

trigonal structure and β-Si_3N_4 with a hexagonal structure. Whiskers are available in a wool form with average diameter of 10 µm and in small-diameter needle form. Table 1 lists some commercially available Si_3N_4 whiskers and their characteristics.

Production and Structure. A variety of methods have been reported for the formation of α- and β-Si_3N_4 whiskers. In the majority of these methods, the VLS mechanism was found to be responsible for whisker growth. GRIBKOV et al. formed α-Si_3N_4 whiskers from a mixture of SiO_2 and Si in an $N_2 + H_2$ atmosphere and found droplets of Fe – Si or Al – Si alloy at whisker tips [64]. HAYASHI et al. nitrided the $SiO_2 - C - Na_3AlF_6$ system and obtained a whisker product containing ca. 85 % β'-sialon whiskers and 15 % α-Si_3N_4 whiskers [65]. Again, the presence of droplets at whisker ends pointed to a VLS growth mechanism.

Following a similar process to that of HAYASHI et al., WANG and WADA also obtained β'-sialon and α-Si_3N_4 whiskers, in both wool-like and short-whisker forms [66]. However, they attributed the growth mechanism to a VS process. They observed that the phases formed depended on the starting materials and the gas flow rate. The major whisker phase was β'-sialon when Na_3AlF_6 was used as the catalyst in the nitridation of SiO_2 and C. These whiskers, which had a rectangular cross-section, an effective diameter ranging from 0.5 to 1.2 µm, and a $\langle 210 \rangle$ growth axis, were believed to have formed by the following reaction:

$$(6-z)SiO(g) + (4-z/2)N_2(g) + (6-2z)CO(g) + zAl(g) \rightarrow Si_{(6-z)}Al_zO_zN_{(8-z)} + (6-2z)CO_2(g) \quad (8)$$

When NaF was substituted for Na_3AlF_6, the major whisker phase became α-Si_3N_4 with a ribbon-like morphology, a width of about 1 µm, a thickness of less than 0.1 µm, and a growth axis along $\langle 211 \rangle$. The following reaction was proposed as the most likely for silicon nitride whisker formation:

$$3\,SiO(g) + 3\,CO(g) + 2\,N_2(g) \rightarrow Si_3N_4(g) + 3\,CO_2(g) \quad (9)$$

WANG and WADA also observed oxynitride (Si_2N_2O) whiskers along with sialon and silicon carbide whiskers, except when SiO_2 was replaced by Si in the starting materials.

The synthesis of β'-sialon whiskers has also been reported in [65,67]. In the latter work, wool-like β'-sialon whiskers, about 1 cm long with diameters of 0.2 – 2 µm, were prepared via a VLS mechanism by carbothermal reaction of silica fume and α-alumina under nitrogen gas. A small amount of $FeCl_3$ was used as catalyst.

GOPALAKRISHNAN and LAKSHMINARASIMHAM prepared α-Si_3N_4 whiskers by nitridation of silicon whiskers with ammonia gas [68,69]. They obtained the silicon whiskers from a gas-phase reaction between $SiCl_4$ and zinc vapor.

HOMENY et al. [70] characterized commercial β-silicon nitride whiskers from Ube Industries (Table 1). These whiskers are found to be close to stoichiometic silicon nitride of an entirely β-Si_3N_4 phase, with oxygen and yittrium as the major impurities. They grow along the [001] axis and exhibit remarkable perfection.

4.3. Alumina and Mullite Whiskers

General Characteristics and Uses. Among the oxide whiskers, mullite and alumina whiskers are the most widely studied for the reinforcement of ceramics, particularly zirconia [17]. The low thermal conductivity of alumina and mullite also makes them excellent candidates for thermal insulation applications. Indeed, the development of Saffil staple alumina fiber with a diameter of about 3 µm by ICI in the late 1960s was in response to the need for larger diameter refractory fibers to replace submicron asbestos fibers as thermal insulating materials.

Mullite is the only crystalline phase in the aluminosilicate system that is stable over a wide range of composition and temperature; the composition can range from $3\,Al_2O_3 \cdot 2\,SiO_2$ to $2\,Al_2O_3 \cdot SiO_2$. Its low coefficient of thermal expansion, low creep rate, and good thermal and chemical stability (it is stable under both oxidizing and reducing atmospheres) make it a very attractive material as reinforcement for ceramics. The common structure for mullite is orthorhombic, with the lattice parameters a, b, and c changing almost linearly with composition. However, tetragonal mullite has also been observed under certain conditions. The coefficient of thermal expansion of mullite also varies almost linearly with its composition [71]. The coefficient

of thermal expansion of mullite with a 2 : 1 composition (i.e., $2\,Al_2O_3 \cdot SiO_2$) is lower and less anisotropic than that of the 3 : 2 composition.

Production and Structure. Sapphire (α-Al_2O_3) whiskers have been manufactured in a wool form with a diameter of 1 – 3 µm as well as in ribbon and needle forms. The strength of sapphire whiskers decreases with increasing whisker diameter [72]. The strength improves considerably when the surface flaws are removed by chemically polishing the whiskers in, for example, orthophosphoric acid [73].

Okada and Otsuka were among the first to prepare mullite whiskers [74]. They used tetraethoxysilane and aluminum nitrate nonahydrate as starting materials to make mullite precursor xerogels. The xerogels were then calcined, mixed with AlF_3, and pyrolyzed at 700 – 1600 °C to give mullite whiskers. The role of AlF_3 was to generate SiF_4 which served as a catalyst for the reaction and lowered the conversion temperature. The whiskers were reported to have grown along the $\langle 001 \rangle$ axis perpendicular to the $\{110\}$ plane, similar to the orientation of natural mullite. Whiskers fired at 1100 °C had a high aspect ratio and a thin cross-section of ca. 0.1 µm; those fired at 1600 °C grew to several tens of micrometers in length. The whiskers were found to be rich in alumina (ca. 80.2 wt % Al_2O_3), which was attributed to loss of silica.

Moyer and Rudolf prepared alumina-rich mullite whiskers by the pyrolysis of fluorotopaz [75]. Fluorotopaz was obtained by heating a mixture of κ-alumina (from the calcination of aluminum hydroxide) and silica above 600 °C in a tetrafluorosilane atmosphere:

$$2\,Al_2O_3 + SiO_2 + SiF_4 \rightarrow Al_2F_2SiO_4 \qquad (10)$$

Mullite whiskers, formed during the pyrolysis of fluorotopaz in the 1050 – 1400 °C temperature range, had about 76 wt % alumina (i.e., 1.88 $Al_2O_3 \cdot SiO_2$). Alumina enrichment was believed to have occurred during the pyrolysis stage as the fluorotopaz had a similar composition to the starting materials. Moyer and Rudolf further reported similarities between mullite compositions prepared from the pyrolysis of fluorotopaz and from melt. Slow cooling of a melt containing 70 – 77.5 wt % Al_2O_3 yields whiskers with 77.2 wt % alumina. Rapid quenching of the melt containing 71.8 wt % alumina, on the other hand, produced mullite with 80 wt % alumina. This led Moyer and Rudolf to suspect a liquid-phase mechanism for mullite formation from fluorotopaz.

Merk and Thomas [76] characterized the structure and composition of mullite whiskers made by pyrolysis of fluorotopaz [77] and the ancient Indian "wootz" obtained from a mixture of clay and rice hulls [78]. They reported a strong dependence of the structure of mullite whiskers on the processing conditions. Whiskers derived from fluorotopaz had a tetragonal symmetry and a thickness ranging from 0.2 to 0.4 µm; the metastable tetragonal phase transformed to orthorhombic upon heating the whiskers in vacuum at 1400 °C. Those obtained from wootz were orthorhombic with a thickness of only 10 – 30 nm. They observed that annealing in vacuum of both types of whiskers resulted in a continuous loss of silica and finally the complete conversion of mullite whiskers to α-alumina powder.

4.4. Aluminum Borate Whiskers

Aluminum borate ($Al_{18}B_4O_{33}$) whiskers were developed in 1987 by Shikoku Chemical Co. in Japan and are commercially available under the tradename ALBOREX-G. The mechanical properties of these whiskers are comparable to those of SiC and Si_3N_4 whiskers while their coefficient of thermal expansion is much lower (Table 1). The major advantage of aluminum borate whiskers over other commercially available reinforcing whiskers is their cost, which is significantly less, by a factor of at about 20, than other whiskers. Aluminum borate whiskers are very suitable for reinforcement of a variety of aluminum alloys [13, 79]. Aluminum-matrix composites reinforced with aluminum borate whiskers have shown a very low coefficient of thermal expansion and good abrasion resistance.

4.5. Other Types of Reinforcing Whiskers

Besides the whiskers described above, a number of other whiskerous materials have been introduced for use as reinforcement in ceramics,

metals or polymers. A cobweb whisker of amorphous SiO_2 with a silicon core has been commercialized by J. M. Huber Corporation under the designation XPV1 [72]. Cobweb whiskers are defined as single crystal fibrous materials with diameters below 0.1 µm. The XPV1 whisker has a diameter of about 10 nm. These whisker-like fibers are expected to have extremely high strengths due to their small size and have demonstrated great efficiency in reinforcing polymer matrices, where they can be used on their own or together with large-diameter fibers.

5. Whiskers for Electronics Applications

5.1. Carbon Whiskers

General Characteristics and Uses. Carbon whiskers have the highest specific strength and specific Young's modulus among all existing reinforcements. In addition, their very high electrical conductivity makes them excellent candidates as conducting fibers for polymeric materials. Polymers with carbon fillers have been considered for a variety of applications such as electrodes for carbon – polymer batteries, pressure sensors, electromagnetic shielding, etc. [80, 81]. The percolation theory has been widely used to predict the transformation of the conducting filler – polymer composite from an insulator to a conductor [82, 83].

Production and Morphology. One method of carbon whisker growth is by catalytic chemical vapor deposition in which C_2H_4 gas is decomposed in the presence of Cu – Ni catalyst at 400 – 600 °C [80, 81]. The degree of graphitization of carbon increases with temperature. Hence, whiskers grown at 600 °C are expected to have lower resistivity than those grown at 400 °C. Whiskers formed at 400 °C following the above procedure are reported to have an average diameter of 0.25 µm and a highly coiled morphology, while those prepared at 600 °C are less coiled, have a larger average diameter of 0.5 µm and a greater aspect ratio. A somewhat similar process was also followed by Motojima et al. who reacted a gas mixture of acetylene, sulfur compound, hydrogen, and argon at a temperature of 750 °C in the presence of nickel powder as catalyst [84]. The product of their reaction, however, was a highly microcoiled carbon fiber, rather than whisker, with a variety of coiling patterns and a low bulk resistivity. One of these patterns is shown in Figure 6.

Figure 6. Coiled carbon fibers [84]

Since the discovery of fullerenes [85, 86], a host of novel carbon structures and morphologies have been obtained. Among these are buckytubes, which are nanotubes with closed ends [87, 88] and fullerene onions [89]. Wang et al. have been able to prepare open-ended carbon nanotubes in a one-step process using hydrogen arc discharge [90].

5.2. Other Types of Whiskers for Electronics Applications

Besides carbon whiskers, which have potential uses as both reinforcements and conducting fillers, a number of other whiskers of conducting, semiconducting, and superconducting materials have also been prepared. However, none of these whiskers is yet commercially available.

Aluminum nitride whiskers have been prepared by the carbothermal reaction of alumina and carbon powder at 1800 °C [91]. Whiskers thus grown are reportedly long and straight single crystals free of planar defects. They have a diameter of about 2 to 30 µm and a length in the centimeter range. Because of its high thermal conductivity, low thermal expansion coefficient, high electrical resistivity, and good dielectric properties, aluminum nitride is considered for semiconductor substrate applications.

Thick whiskers of tin oxide (SnO_2), which is used as a semiconducting sensor to detect H_2, CO, town gas, alcohol, etc., are prepared by heating a mixture of SnO_2 and tin powders at 1200 °C in air [92]. Depending on the processing conditions, these whiskers can be ribbon-shaped with a thickness of ca. 150 µm and growth direction of [010] or dendritic with rugged surfaces [93]. The dendritic whiskers exhibit a much greater hydrogen sensitivity than ribbon-shaped whiskers with smooth surfaces. The greater hydrogen sensitivity of the former morphology is attributed to its stepped surfaces.

Cadmium oxide (CdO) whiskers are grown on a CdS substrate via a VLS mechanism [94]. In this process, the surfaces of the CdS crystal are coated with a thin layer of metal catalyst (Si, Pd, Ag, Au, Al, Ni, or Pt). The coated crystals are then annealed in air at 670 – 730 °C, whereby whiskers appear on the CdS surface. In terms of the growth efficiency, the best results are reported with Au, Ag, and Pd coatings. Whiskers thus grown have a face-centered cubic lattice and their morphology largely depends on the metal catalyst used. The largest whiskers, ca. $2\times0.1\times0.01$ mm, are obtained with Au; these whiskers are parallelepiped with $\{100\}$ faces. Figure 7 shows CdO whiskers grown on CdS substrate with Ag coating.

Figure 7. CdO whiskers grown on CdS crystal substrates using Ag as the catalyst [94]

In high-temperature superconductivity grain boundaries are a hindrance to achieving high critical currents. Approaches are hence taken to eliminate or minimize grain boundaries. One such approach is the use of whiskers. Upon the discovery of glass formation in the Bi – Sr – Ca – Cu – O (BSCCO) superconducting system, efforts have been made to form whiskers of these materials via a glass-ceramic processing route. Matsubara and co-workers have successfully prepared whiskers of $Bi_2Sr_2CaCu_2O_x$, known as the 2212 phase, by heating glassy melt-quenched plates of the BSCCO system doped with Al [95], Li [96], and Ga in flowing oxygen. The phases, morphology, and superconductivity of the whiskers thus obtained depend greatly on the processing conditions and the type of dopant used. Whiskers obtained with Al are reported to be plate-like single crystals about 1 – 5 µm thick, 10 – 100 µm wide, and up to 20 mm long. These are primarily the 2212 phase with about 1 % $Bi_2Sr_2Ca_2Cu_3O_x$ (2223) phase. Ga doping produces much shorter (ca. 1 mm) whiskers. Whiskers exhibit enhanced superconductivity with Li as the dopant. Kasuga et al. also prepared 2212 whiskers by heating a compacted mixture of melt-quenched $Bi_2Sr_yCa_1Cu_2O_x$ powder and alumina powder [97]. The magnitude of the pressure applied for compacting the powders was found to be an important factor in whisker growth. Whiskers obtained from specimens compacted at 20 MPa were less than 1 mm long while those grown from specimens compacted at 180 MPa were 1 – 5 mm in length.

6. Toxicology and Occupational Health

It is now well established that asbestos fibers which have a diameter less than 1 µm and aspect ratio greater than five cause irritation of the eyes, skin, and pulmonary system and may even lead to pulmonary fibrosis and cancer. Studies on the potential health hazards of other types of fibrous particles with submicron diameters are very limited. However, it is likely that whiskers may also pose health hazards similar to those of asbestos [98]. Therefore, it is highly recommended that precautions be taken during processing and handling of whiskers to avoid breathing them or releasing them into the work area and clothing. Similar care must also be exercised during cutting, machining, or other manufacturing opera-

tions that could release them into the work environment.

1. Introduction

The term whiteware was originally applied to white tableware and artware. It is now used for all ceramic ware that is ivory colored or has a light grey appearance in the fired state. Fine ceramic whitewares are conveniently divided into two classes:

1) Triaxial bodies, consisting primarily of the three components: clays, feldspathic materials, and quartz
2) Nontriaxial bodies made entirely or predominantly of other materials

The whiteware group can be divided into five categories: earthenware; stoneware; china; porcelain; and technical ceramics.

This article covers mainly earthenware, china, porcelains, and technical ceramics (the latter in so far as they are based on clays and other silicates). Stoneware is mostly a colored type of ceramic ware and it is treated elsewhere (→ Construction Ceramics). Technical ceramics comprise silicates and materials based on oxides, carbides, nitrides, and similar compounds (→ Ceramics, Electronic).

2. Definitions and Classification

The ASTM standard C 242-92 gives the following definition of whitewares:

Ceramic Whiteware. A fired ware consisting of a glazed or unglazed ceramic body which is commonly white and of fine texture; designating such product classifications as tile, china, porcelain, semivitreous, and earthenware.

Some definitions taken from ASTM C 242-92 and essential to this article follow:

Body. The structural portion of a ceramic article, or the material or mixture from which it is made.
Bone china.
A translucent china made from a ceramic whiteware body composition containing a minimum of 25 % bone ash.
Ceramic article. An article having a glazed or unglazed body of crystalline or partly crystalline structure, or of glass, which is produced from essentially inorganic, nonmetallic substances and either is formed from a molten mass which solidifies on cooling, or is formed and simultaneously or subsequently matured by the action of heat.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_243

Ceramic process. The production of articles or coatings from essentially inorganic, nonmetallic materials, the article or coating being made permanent and suitable for utilitarian and decorative purposes by the action of heat at temperatures sufficient to cause sintering, solid-state reactions, bonding, or conversion partially or wholly to the glassy state.
Ceramics. A general term applied to the art or technique of producing articles by a ceramic process, or to the articles so produced.
China. A glazed or unglazed vitreous ceramic whiteware made by the china process and used for nontechnical purposes, designating such products as dinnerware, sanitary ware, and artware when they are vitreous.
China sanitary ware.
Glazed, vitrified whiteware fixtures having a sanitary service function.
Decoration.
Inglaze decoration. A ceramic decoration applied on the surface of an unfired glaze and matured with the glaze.
Overglaze decoration. A ceramic or metallic decoration applied and fired on the previously glazed surface of ceramic ware.
Polychrome decoration. A multicolor decoration.
Underglaze decoration. A ceramic decoration applied directly on the surface of ceramic ware and subsequently covered with a transparent glaze.
Dinnerware. Ceramic whiteware made in a given pattern and in a full line of articles comprising a dinner service.
Earthenware. A glazed or unglazed nonvitreous ceramic whiteware.
Electrical porcelain. Vitrified whiteware having an electrical insulating function.
Frit. A product made by quenching and breaking up a glass of a specific composition, used customarily as a component of a glaze, body, or porcelain enamel.
Glaze. A ceramic coating matured to the glassy state on a formed ceramic article, or the material or mixture from which the coating is made.
Impervious. That degree of vitrification evidenced visually by complete resistance to dye penetration.
Jasper ware.
A vitreous, opaque, colored, unglazed ceramic ware having white or contrasting relief decorations and containing a substantial amount of barite.
Majolica.
Formerly an earthenware with an opaque luster glaze and overglaze colored decorations, but currently designating any decorated earthenware having an opaque glaze.
Mullite porcelain.
A vitreous ceramic whiteware for technical applications in which mullite ($3\,Al_2O_3 \cdot 2\,SiO_2$) is the essential crystalline phase.
Mullite whiteware.
Any ceramic whiteware in which mullite ($3\,Al_2O_3 \cdot 2\,SiO_2$) is the essential crystalline phase.
Oven ware.
Ceramic whiteware for culinary oven use.
Porcelain. A glazed or unglazed vitreous ceramic whiteware made by the porcelain process, and used for technical purposes, designating such products as electrical, chemical, mechanical, structural, and thermal wares when they are vitreous.
Porcelain process. The method of producing glazed ware by which a ceramic body and glaze are matured together in the same firing operation.
Pottery.
All fired ceramic wares that contain clay when formed, except technical, structural, and refractory products.
Semiporcelain.
A trade term designating semivitreous dinnerware.
Semivitreous (semivitrified). That degree of vitrification evidenced by a moderate or intermediate water absorption.
Stoneware.
A vitreous or semivitreous ceramic ware of fine texture, made primarily from nonrefractory fireclay.
Tableware.
All utensils and decorative articles used on the table for meal service.
Vitreous (vitrified). That degree of vitrification evidenced by low water absorption.

Certain terms have developed different meanings in various countries. In the United Kingdom and the United States, ceramics comprises all

inorganic nonmetallic materials. In Central Europe the term *Keramik* is restricted to materials which meet the following conditions [21–23].

1) They are inorganic and nonmetallic
2) They are partially or completely crystalline, 30 % crystallinity being the lower limit
3) They are insoluble in water
4) They are heated to high temperatures during production or use; in modern ceramic materials, heating above 900 °C is necessary to produce the desired structure and properties

In this article, ceramics has the meaning of the German term *Keramik*, i.e., it excludes glass and glass ceramics.

Ceramics are classified according to grain size (body texture), vitrification, body color, translucency, and porosity. Bodies with grain size >0.1 mm appear inhomogeneous to the naked eye; the German term for products with this coarse body texture is *Grobkeramik* (= coarse ceramic). This generic term includes various groups of products, e.g., bricks, tiles, and refractories. In the field of tableware, the nearest equivalent in English is common pottery, a term recognized internationally for tariff purposes. Bodies with grain size <0.1 mm appear uniform in texture, even when they are really inhomogeneous on a microscopic scale. The German term for products with this fine body texture is *Feinkeramik* (= fine ceramics). There is no equivalent in English. The term fine ceramics has been introduced in Japan to summarize materials based on oxides, carbides, nitrides, and other materials, used for advanced applications. This differs fundamentally from the German concept of *Feinkeramik*. The clay-based materials in the group *Feinkeramik* are further classified according to color and porosity:

Common pottery: colored, porous
Earthenware:
white or at least bright, porous
Stoneware: colored, vitrified
China or porcelain: white, translucent, vitrified

The distinction between porous and dense structures is made on the basis of water absorption; dense materials have water absorption < 2 wt %.

In the United Kingdom, the terms china and porcelain are synonyms when applied to the classification of tableware. Bone china is defined simply as a special composition with a minimum tricalcium phosphate content within the china and porcelain classification. The key property requirements for tableware in this classification are a very low water absorption (corresponding to a high degree of vitrification), a white body, and translucency in thin sections. Thus, the same properties are recognized in the United Kingdom as in Germany in the definition of *Porzellan*.

The definitions of ASTM C 242-92 are similar in scope to the German definitions, but distinctions between materials are not made on a quantitative basis, and difficulties may arise in finding equivalent English and German terms.

The term porcelain is also used for technical ceramics in the United Kingdom and the United States. For example, in the United Kingdom, it is used for electrical porcelain which is vitrified, but not translucent.

Porcelain, as defined in ASTM C 242-92, comprises certain special types of technical ceramics, e.g., cordierite, forsterite, steatite, titania (titanium dioxide), and zircon porcelain. In some countries, porcelain is generally classified as a luxury article for tariff purposes, regardless of the real type of ware; this can be a serious obstacle to international trade in some types of technical ceramics, and whiteware seems to be the preferable term. These materials can be defined as special types of ceramic whitewares, avoiding their classification as types of porcelain. A European standard for classification of materials used for tableware is in preparation. No generally accepted agreement has been reached so far, partly because of the uncertain classification of "borderline" materials, and partly because of traditional assignments of certain materials to special groups. Porcelains may have a residual porosity up to 0.5 % according to the draft European standard, although any porosity impairs translucency.

Bruno Sanders [24] introduced the following German terms for the characterization of materials:

Gefüge:
all characteristics which can be used for the description of a material, e.g., structure, including microstructure
Struktur:

characteristics which are independent of direction
Textur:
characteristics which depend on direction, e.g., orientation

No systematic use of analogous terms can be observed in British or American English; texture may be used to describe properties that are independent of direction while structure is preferred to summarize properties which depend on direction. To avoid confusion, German terms are used here when they are more clearly defined than the English ones.

3. Porous Whitewares: Earthenware

Porous ceramics are often classified according to their body color. The colored types are sometimes called pottery, whereas the white-bodied types discussed here are classified as earthenware.

Earthenware was developed by Josiah Wedgwood in the 18th century. He introduced china clay to obtain a cream-colored ceramic body.

Nowadays earthenware is used for wall and floor tiles, and for tableware and fancy goods. Its main advantages are a broad range of decorative colors and low production cost. The lower mechanical strength compared with china can be a disadvantage for certain applications. For other uses earthenware has been replaced by stoneware or soft porcelain, avoiding problems associated with the porous structure of earthenware.

3.1. Types of Earthenware

Earthenware can be classified according to body composition. The main types are clay earthenware, lime earthenware, and feldspathic earthenware.

Clay earthenware is the oldest type; it uses clays which are not too high in iron oxide, but fairly rich in fluxing impurities. Flint or sand is generally added.

Lime earthenware contains 5 – 35 % lime, introduced either by the use of natural marl (*Mergel*) or by the addition of carbonates such as limestone, chalk, or marble to the clay body. Dolomite is also sometimes used. Free silica is added as a further ingredient.

Feldspathic earthenware contains 5 – 20 % feldspathic material, introduced as beneficiated soda or potash feldspar, or nepheline syenite, or, in an impure form, as arcose sands; the remainder consists of ca. 50 % ball clays and china clays, and up to 45 % free silica. Feldspathic earthenware is the type preferred in England.

Other types of earthenware depend on the use of special raw materials: talc earthenware with the addition of up to 60 % talc, and mixed earthenware which contains a mixture of lime and feldspar as a flux.

3.2. Structure and Properties

Firing of earthenware is executed at fairly low temperatures; the mixture of raw materials consolidates to a ceramic body, but does not vitrify completely, so that the fired body has some porosity. For most applications the pores have to be sealed by glazing the body. Reliable sealing demands a glaze without any crazing, even over long periods; this requires a glaze well matched in its thermal expansion to the body.

The mineral phases in the final structure of earthenware (excluding residues of the minerals introduced in the crude body) develop partly by thermal transformation of the original minerals and partly by thermal reactions between them (Fig. 1).

The mineral phase composition of the final body, including the pores, controls the properties of earthenware.

Glazes with a melting temperature $<1100\,^{\circ}C$ have a rather high thermal expansion coefficient, exceeding that of mullite or amorphous phases in the ceramic body. To match the thermal expansion coefficients of body and glaze, special measures must be adopted, either by actuating reactions in the ceramic body during firing (which result in phases of higher thermal expansion) or by addition of materials with high thermal expansion coefficients which are preserved during firing. Suitable reactions during firing include the formation of cristobalite or anorthite. Mineral phases introduced via the raw materials and capable of increasing the thermal expansion of

Figure 1. Reactions occurring in bodies of earthenware during firing

the body include quartz and especially cristobalite.

Higher amounts of fluxes in the crude body and increasing firing temperatures result in an enhanced formation of melting phases during firing. The process has to be balanced between sufficient consolidation of the body and controlled dissolution of minerals which have been added to yield high thermal expansion.

Even when the glaze adheres initially under slight compressive stresses, the system can develop crazing over longer periods. This is a consequence of moisture absorption and of reactions of water vapor with the amorphous phases in the ceramic body, causing a slight volume increase known as moisture expansion. If this moisture expansion of the body puts the glaze under tension, it crazes. Complete sealing of the body can prevent it from absorbing moisture. The reactivity of the amorphous phase with water vapor depends on its chemical composition: alkaline earth oxides, iron and manganese oxide reduce the sensitivity to moisture expansion. Lime earthenware and the iron-bearing types of pottery are less susceptible to moisture expansion.

3.3. Raw Materials

Ball Clays. Clays are the essential raw materials for earthenware because they render the body plastic and thus suitable for ceramic fabrication processes; highly plastic clays are preferred. Other important requirements are that they develop a white or bright fired color, i.e., they have low iron oxide content, and do not contain pyrite, which causes dark spots in the fired body. Earthenware clays should not vitrify when fired at ca. 1200 °C. Suitable clays have restricted amounts of minerals which act as fluxes. Kaolinitic clays of the sedimentary type containing some quartz are preferred for earthenware production. Some organic matter may increase their suitability for casting processes.

China clays can replace ball clays up to around half of the total plastic component, contributing to the bright fired color. To reduce costs, crude kaolins can be used instead of washed kaolins.

Quartz and Flint. Quartz is used in earthenware bodies to control the drying sensitivity and to match the thermal expansion of the fired material to that of the glaze. Flint tends to transform rapidly to cristobalite, even when fired at rather low temperatures; transformation starts at

ca. 1050 °C. They are the preferred raw materials in earthenware production in England. Siliceous earth from Neuburg on the Danube is used occasionally as a raw material in earthenware for similar reasons.

Feldspathic Raw Materials. Feldspar is used as a flux in earthenware. All types of sodium feldspar, potassium feldspar, and mixed feldspars are suitable.

For reasons of cost, arcose sands (occasionally incorrectly named pegmatites) can be used as a source of feldspars. They have to fire brightly, without spots.

Sources of Alkaline Earth Oxides. Alkaline earth carbonates (e.g., limestone, chalk, dolomite) are the preferred sources of alkaline earth oxides; they have to be rather fine grained to stimulate complete reaction with other components during firing, anorthite ($CaAl_2Si_2O_8$) and diopside [$CaMg(SiO_3)_2$] being the main reaction products; free calcia and magnesia cause the subsequent formation of cracks because of their reaction with water.

In the United States, natural wollastonite ($CaSiO_3$) is sometimes used as a raw material in earthenware bodies. Attempts to use synthetic alkaline earth silicates in earthenware production have failed because of their high cost.

In countries with suitable sources of talc [$Mg_3Si_4O_{10}(OH)_2$] this mineral can be used as a source of magnesia in earthenware bodies, which leads to the special type of talc earthenware.

Availability of Raw Materials. In temperate climates raw materials for earthenware production are generally available.

3.4. Fabrication of Tableware and Fancy Goods

The preferred type of earthenware for tableware and fancy goods is feldspathic earthenware.

Body Preparation. The feldspar and filler materials (quartz, sand, calcined flint) are ground in wet ball mills or purchased in a suitable grain size. The clays and kaolins are suspended in a blunger. The slurry is mixed thoroughly with the ground nonplastic materials, and subsequently dewatered in a filter press. The filter cakes are then homogenized in a deairing pug mill to obtain the plastic body for forming. Slips needed for casting processes are prepared from the filter cakes by adding an appropriate amount of water and deflocculant.

The more modern process of isostatic pressing needs granulates which are preferably produced by spray-drying batch slurries. Spray-dried granulates are also used to reduce transport costs; they are redispersed in the tableware factory to form casting slips or plastic bodies.

Figure 2. Principles of ram-presssing of earthenware articles
Sequence of steps during ram-pressing: A) Insertion of a body lump into the mold; B) Pressing process for execution of forming, water removal by vacuum in the mold; C) Opening of the mold, vacuum at the upper part, pressure at the lower part of the matrix; D) Removal of the pressed part, pressure at the upper part of the mold
a) Mold made from plaster of Paris; b) Lump of body; c) Mold with applied vacuum; d) Mold with applied pressure; e) Pipe system in the mold

Forming Processes. Casting is performed in the usual manner, with plaster molds.

Plastic forming of earthenware comprises extrusion and jiggering and jollying with roller machines. A further forming process especially for earthenware, is ram-pressing (Fig. 2) which uses a porous mold. Water is sucked off by vacuum; removal of the pressed body from the matrix is assisted by compressed air. Isostatic pressing has

also become an important forming process for earthenware.

Drying and Firing. The drying process is equivalent to that for all ceramic articles.

Firing of earthenware has its own characteristics: biscuit firing is executed at higher temperatures than glost firing. In biscuit firing, the ware is heated to Seger Cone 8 (ca. 1240 °C) where the body develops its final microstructure. Biscuit firing of plates can be executed in stacks because of the lack of molten phase at the surface. Subsequent glazing is easy because of the porous structure of the biscuitware. The subsequent glost firing is executed at Seger Cone 1a – 5 (ca. 1100 – 1180 °C). In order to avoid sticking of the articles to the saggars, they are placed on pins. The contact areas between articles and pins have to be ground smooth after firing.

3.5. Fabrication of Wall and Floor Tiles

Body Preparation. The preferred production method for wall and floor tiles is dry pressing with spray-dried granulate.

Forming Processes. The granulate is compressed in steel dies on special hydraulic presses. The pressing operation has to be adapted to the properties of the granulate to avoid crack formation. This is mainly a matter of experience.

Drying and Firing. Owing to the low moisture content, drying can be rapid. Biscuit firing is preferably carried out in an oxidizing atmosphere, at Seger Cone 6a – 8 (ca. 1210 – 1250 °C), glost firing at 100 – 200 °C lower. The tiles are laid on supports and fired in one layer in fast-firing kilns. Single firing is being introduced to save energy.

3.6. Glazing of Earthenware

3.6.1. Composition and Properties

Glaze is applied, e.g., by dipping (tableware), or by spraying (tiles). Multiple glazing can be applied to give patterned designs.

Glaze properties are controlled by chemical composition, by the types of starting materials used in the glaze, and by details of the application, e.g., thickness of the glaze layer. Important features are:

1) High resistance to crazing, even after long periods
2) Translucency and high gloss, especially for underglaze decoration
3) Hardness and wear resistance
   Resistance to the acids and caustic solutions encountered in household use
4) No health risk from release of toxic ingredients from the fired glaze

The low temperature of glost firing of earthenware necessitates the use of strong fluxes in the glazes which also have to meet other requirements; lead oxide and boron oxide are usual components of earthenware glazes. Alkali oxides are strong fluxes; they involve less health risk, and give a good appearance. However, they increase the thermal expansion of the glaze considerably; it becomes difficult to match it to that of the body, and they can be used only in restricted amounts.

The chemical characteristics of earthenware glazes, as expressed by the Seger formula (→ Ceramics, General Survey, Chap. 5.1.) can range within the following limits:

0.0 – 0.4 K_2O	
0.0 – 0.4 Na_2O	2.0 – 3.0 SiO_2
0.0 – 0.4 CaO	0.2 – 0.3 Al_2O_3
0.3 – 1.0 PbO	0.2 – 0.5 B_2O_3
0.0 – 0.1 MgO, ZnO	

Typically, earthenware glazes use frits as starting materials, offering certain special features:

1) The glost firing temperature is lower than with raw glazes
2) Water-soluble compounds can be fixed in an insoluble frit, so that wet grinding becomes possible
3) Toxic components can be safely fixed in insoluble frits

Colored glazes are obtained by addition of suitable metal oxides, which are dissolved in the melt during firing. The influence on glaze properties has to be considered in the Seger formula. Another possibility is the addition of pigments (→ Ceramic Colorants) which are insoluble in the fused glaze.

Opaque glazes are obtained by addition of special opacifiers such as zircon ($ZrSiO_4$) or by the selection of compositions in which certain components are insoluble, or at most sparingly soluble, in the fused glaze. In other types of glazes, crystallization occurs, which also causes opacity. In crystal glazes the crystals grow to a visible size.

3.6.2. Glaze Stresses

The thermal expansion coefficients of ceramic body and glaze affect the properties critically. Crazing can be avoided when the glaze has a thermal expansion coefficient somewhat lower than that of the body. A suitable difference is a matter of experience. The stresses caused by differences in thermal expansion depend not only on the two thermal expansion coefficients, but also on the relative thickness of the two layers.

Thermal expansion coefficients can be measured with a dilatometer, but it is better to measure the stresses in the combined system, because thermal expansion may be modified by reactions between the two layers during firing. An instrument to provide this information has been designed by STEGER. It measures the bending caused by stresses resulting from the mismatch in thermal expansion.

4. Vitrified Whitewares: Porcelain and China

Porcelain and china are types of whitewares which have a white, translucent, dense body. The type used for tableware and artware is termed china or porcelain. The term porcelain is also used to cover those types used in technical applications. Chinas and porcelains are usually coated with a transparent glaze.

China was developed by improving the color of stoneware to white, by an increasing use of white-firing raw materials. A ceramic body which can be considered real china was first produced in China during the T'ang Dynasty (9th century). The fabrication of extremely thin china reached perfection in the Sung and Ming Dynasties. Huge quantities of china were exported to Europe during late Middle Ages and early modern era.

European attempts to develop an equivalent whiteware succeeded in the early 1700s when JOHANN FRIEDRICH BÖTTGER invented hard porcelain (the Chinese produced a soft-paste type).

4.1. Types of China and Porcelain

Two basic types of china can be distinguished: the classical type is based on kaolin, feldspar, and quartz. It is used for tableware as well as in technical applications. The other type, used only for tableware and artware, contains considerable amounts of bone ash as an essential raw material, flux (feldspar) and clay being the other main components. Special porcelains contain other components (e.g., alumina).

According to the firing temperature two types are known. Hard porcelains are fired at ca. 1400 °C (ca. Seger Cone 14), soft porcelains at ca. 1250 °C (ca. Seger Cone 8). The higher the firing temperature, the harder the glaze. The firing range of whitewares is controlled by the amount of flux in the batch.

4.2. Physical Properties

Translucency is an essential property of china. The less light scattered during transmission through the body, the more translucent the china. This depends on the amount and composition of crystals, and also on the number of micropores in the fired structure. This in turn depends on the batch composition, on the purity of the raw materials, and on the firing cycle, which controls dissolution of crystals and removal of pores. Traces of heavy metal oxides impair translucency considerably [25]. To give a translucent fired body, the raw materials should have as little iron oxide and titanium dioxide as possible; these oxides react to form the dark ilmenite ($FeTiO_3$). Ilmenite formation seems to depend on the chemical bonding of iron oxide in the raw materials; iron oxide in the clay minerals seems to be less critical than that present as separate iron minerals, because it becomes incorporated in the mullite structure and does not form ilmenite [26].

Translucency also depends on the dissolution of quartz during firing, which is influenced by

the geological origin of the quartz. Vein quartz is dissolved more rapidly than quartz sand, but its high price prevents its widespread use.

The melt in the porcelain body picks up quartz during firing; it becomes depleted in alumina, and thus takes up mullite (alumina silicate) to reach equilibrium; this increases translucency. Oversaturation of the melt with silica causes the crystallization of cristobalite, increasing the number of scattering centers in the body, and thus reducing translucency [27].

Alumina, introduced as corundum, is scarcely dissolved in the melt during firing, and thus decreases translucency.

Bone china is fairly high in translucency, despite its rather high crystallinity. The refractive index of the crystalline phases (β-tricalcium phosphate and anorthite) approaches that of the glass phase, and thus scattering of light is low.

Whiteness of chinas is affected mainly by the purity of the raw materials. Besides the iron oxide content, the titanium dioxide content has proved to be critical because titanium dioxide intensifies the coloring effect of iron oxide, although colorless itself [27,28]. The chemical bonding of iron oxide in the raw materials also affects the whiteness of porcelains.

Another important feature for the color of the fired body is the firing atmosphere. In a reducing atmosphere, the iron oxide present in traces in all raw materials is reduced to the divalent state, the color of which is negligible. When the atmosphere at maximum firing temperature is oxidizing, iron remains in the trivalent state which causes an ivory to yellow color of the fired body.

Thermal Properties. Porcelains and chinas are used mainly at room temperature. In principle, their use at elevated temperatures ends when the vitreous phase begins to soften, at ca. 800 °C. An increase in mechanical strength is observed as porcelain is heated to this temperature range because of healing of microcracks.

Thermal shock resistance determines the use of china as ovenware or cookware and in chemical engineering, as well as the suitability of porcelain insulators for outdoor use. Thermal shock resistance is controlled mainly by thermal expansion behavior. The thermal expansion coefficient of porcelains ranges around $(4-6)\times 10^{-6}\,\mathrm{K}^{-1}$, which is rather low compared with other ceramic materials or even metals or plastics. Thus thermal shock resistance is quite good. It is however impaired by the sudden volume change of quartz during its $\alpha-\beta$ transformation at 573 °C, or the cristobalite phase change above 200 °C. Porcelains intended for applications where thermal shock can occur, e.g., in chemical engineering, should have low quartz content.

The increase in volume of quartz and cristobalite during heating makes it easier to find glaze compositions which ensure a lower thermal expansion coefficient of the glaze compared with the body, thus providing surface compressive stresses. This can be used to produce glazed porcelain articles with increased mechanical strength.

Mechanical Strength (Table 1) is important, especially with porcelains used for electrical insulators. The various porcelain types used in this field are standardized in IEC 672. Type C-110 is a traditional triaxial quartz porcelain. Type C-111 is a triaxial porcelain produced by pressing, containing up to 3 % porosity, whereas otherwise porcelains have to be completely vitrified to zero open porosity. Type C-112 is a porcelain which contains cristobalite instead of quartz in its fired structure. Types C-120 and C-130 are alumina porcelains with different amounts of corundum in their structures. The higher the alumina content, the better the mechanical strength, but the fabrication process is more difficult. Type C- 120 is preferred for fabrication of electrical insulators and in other engineering applications.

The figures in Table 1 are valid only for special test bars (see part 2 of IEC 672). Corrections have to be made if the mechanical strength of real components is to be estimated. Strength decreases as the diameter of the component increases.

Mechanical strength is improved considerably by glazing when the thermal expansions of glaze and body are well matched (see above). A glaze somewhat lower in thermal expansion than the body causes compressive stresses at the surface, which improve mechanical strength. When an external tensile stress is applied, the surface compressive stresses in the glaze must to be overcome before a tensile stress of a magnitude

Table 1. Minimum bending strength of porcelains according to IEC 672

Type	C-110	C-111	C-112	C-120	C-130
Bending strength, unglazed, N/mm^2	50	40	80	90	140
Bending strength, glazed, N/mm^2	60		100	110	160

sufficient to cause a catastrophic breakage can occur.

No requirements for tensile or compressive strength are standardized in IEC 672 because of the high scatter of measurements of these properties. It is estimated that the tensile strength of ceramic components is about half the bending strength, and the compressive strength is about ten times the bending strength. This suggests the design of ceramic components which are preferably stressed by compression.

The mechanical strength of various porcelain types is related to their batch compositions. In triaxial porcelains, a minimum strength is observed for the traditional types (ca. 25 % quartz); types of lower and higher quartz content have considerably higher strength [29]. The relationship between strength and quartz content can be explained by structural stresses resulting from the mismatch in thermal expansion of quartz and the vitreous phase in the porcelain body [30–32]. The structural stresses in the vitreous phase are tensile stresses perpendicular to the surface of the quartz grains, but compressive shear stresses along the boundaries. Increasing the amount of quartz results in a decrease of the tensile stress and an increase of the compressive shear stress around each quartz grain. Taking into account the amount of quartz, it is possible to deduce that a minimum strength will occur at a medium quartz content [30–32]. This agrees with practical experience [29].

The influence of alumina on strength can be ascribed to another mechanism. Corundum has a high Young's modulus; therefore, external stresses cause only little strain. The surrounding vitreous phase is relieved of deformation when external stresses are applied. As corundum crystals have a high internal strength, breakage occurs only at rather high external stresses.

The mechanical strength of bone china ranges between types C-110 and C-120 (IEC 672). This can be explained by the lack of crystals which would cause structural stresses and cracks, as well as absorbing external stresses by their high Young's modulus. No values are standardized as bone china is used only for tableware and artware.

Electrical Properties. Porcelain has been widely used for electrical insulators since the beginning of electric power transmission. Similar to other dense ceramic materials, porcelains have an excellent electric strength; the 1-min withstand voltage at 50 Hz under standardized test conditions is >30 kV. Another important feature of porcelains is the high leakage current resistance. Electric spark discharges do not cause damage which would result in a conductive surface layer.

The electrical dissipation factor at 10^6 Hz is ca. 10^{-2}; porcelains are not normally used as insulating materials in high-frequency electrical engineering. More suitable in this field are special types such as the alkaline earth porcelains. (No other uses of these porcelains are known because of their narrow range of firing temperature, which restricts them to articles of small size.)

4.3. Chemical Properties

Porcelains are generally resistant to attack by acids (except hydrofluoric) and organic liquids. Concentrated alkaline solutions attack porcelains; attack increases exponentially with concentration of the corrosive solution and with temperature [33]. A combination of chemical attack and mechanical abrasion may be more severe, and should be considered when using porcelain devices in chemical engineering.

4.4. Raw Materials (→ Ceramics, General Survey, Chap. 1.3., → Ceramics, General Survey, Chap. 2.)

Kaolins (→ Clays). Kaolins (china clays) are residual clays, usually found in primary deposits.

The kaolins used for the production of china and porcelain should have high plasticity, high dry strength, good deflocculation behavior for use in casting slips, and high whiteness in the fired state. Whiteness is controlled by low iron oxide and titanium dioxide, and by chemical bonding (Section 4.2). Dry strength and plasticity are influenced by type and amount of mixed layer minerals, which are present in small amounts in many kaolins, especially in those suitable for use in porcelain fabrication. Deflocculation behavior is closely related to ion-exchange capacity. The broad variety of deflocculants available makes it possible to find a suitable one for most kaolins.

The kaolins used in china and porcelain production are normally processed to remove sand and micas, which can be present in natural kaolins in large quantities. Small residual amounts are less critical than in filler applications so that a classification with a cut at 20–40 μm and thus with less preparation steps gives a satisfactory quality.

Normally, mixtures of various kaolins are used in china and porcelain batches to ensure reasonably constant composition and properties, and to adjust these to production requirements. To improve plasticity, small amounts of ball clays may be added; the amount is limited by the need to keep iron oxide and titanium dioxide low. In technical porcelains, this is less critical; the amount of white-firing ball clays can be increased up to ca. 15 % to improve workability of the crude body; kaolinitic secondary clays are suitable.

Feldspars. The favored type of feldspar in china and porcelain production is potassium feldspar ($KAlSi_3O_8$), which forms a melt of higher viscosity at a given temperature compared with sodium feldspar, and thus causes less deformation during firing. Moreover it allows a broader range of firing temperature [34, 35]. Calcium feldspars are scarcely used in ceramics because of their extremely narrow range of firing temperature.

The high fluxing effect of sodium feldspar is taken advantage of in glazes to assist their flow at temperatures where the body has to remain rigid.

The feldspars used in ceramics are preferably those generated in the pegmatitic phase of magmatic differentiation, because of their high purity and easy processing. Arcose sands, derived from granites by mechanical and chemical weathering, can be used when available in sufficient purity; their fineness reduces the cost of crushing. Moreover they contain feldspars with higher potassium/sodium ratios because sodium feldspars tend to be kaolinized during weathering; these feldspars are even better in preserving stability against deformation during firing. Their quartz content has to be considered in calculating the batch composition.

Nepheline syenite may be used in porcelain bodies instead of feldspar because of its higher alkali content and thus higher fluxing effect; because of its lower availability its use is confined to special types.

Quartz. The preferred silica raw material in china and porcelain production is quartz sand because of its granular structure which reduces crushing costs. Sands of sufficient purity are necessary.

In countries with suitable flint reserves, these are used as a silica source. On preheating, flint becomes brittle which makes crushing easier. The quartz microcrystals are partially transformed to cristobalite which may offer certain advantages because of its influence on thermal expansion.

Vein quartz could be attractive as a raw material because it produces a more translucent china [27]. The high price and the need for expensive crushing processes restricts its use to special products.

Bone ash is an essential ingredient in bone china. The source of supply is mainly ox bone, which has to be freed from organic constituents. The bone is then calcined at ca. 1000 °C. The main crystalline phase in bone ash is hydroxyapatite [$Ca_5(PO_4)_3OH$]. For its use in bone china fabrication, it seems essential to retain a small amount of organic matter in the ash, but too much can be troublesome.

Other Ingredients. Technical porcelains may contain free alumina up to 40 wt % to in-

crease mechanical strength. Alumina is supplied by a specialized chemical industry which offers various types adapted to the needs of the ceramic application.

Zircon ($ZrSiO_4$) has a similar effect on properties to that of alumina [36,37]. Its use is restricted to special cases, especially in countries with large zircon resources.

4.5. Special Types of China and Porcelain

Hard porcelain is the preferred type produced and used in Central Europe. It is designed to be fired at Seger Cone 13 – 16 (1380 – 1460 °C). Its classical type, with ca. 50 % kaolin, 25 % feldspar, and 25 % quartz combines good mechanical strength, low deformation during firing, and good translucency and whiteness.

For applications with thermal shock load, e.g., in cookware or chemical engineering, special types with low quartz content have been developed. Types with increased quartz content up to 40 % exhibit improved mechanical strength; they have tended to be replaced by alumina porcelains, with even higher strength.

Cristobalite porcelain contains cristobalite instead of quartz in the fired structure. This can be achieved by the use of special raw materials, such as chinastone (Japanese, *toseki*) which is available chiefly in East Asia. Chinastone is a rock containing high amounts of micaceous minerals. This contributes to a high plasticity and causes the rapid transformation of the original quartz to cristobalite. Cristobalite porcelains have a mechanical strength exceeding that of quartz porcelains. The special properties can be explained as a consequence of the structural stresses, which are higher than in quartz porcelains, because of the greater mismatch of the thermal expansion of cristobalite crystals and the vitreous phase in the fired body [31]. Cristobalite porcelains are quite common in East Asia because of the availability of chinastone; otherwise alumina porcelains are preferred.

Alumina porcelains are characterized by high mechanical strength. This established their use in the field of technical ceramics, especially for high-voltage insulators. In composition they resemble the hard porcelains, but quartz is replaced by free alumina. The higher the alumina content, the higher the mechanical strength. Superior types contain up to 40 % free alumina. Consequently, fabrication is difficult and wear of fabrication equipment is high.

Soft porcelains contain a higher amount of flux, so they can be vitrified at ca. 1250 °C. Increased flux means a reduction of the clay components, reducing plasticity. To ensure suitable fabrication properties, the kaolin has to be replaced partly by plastic, white-firing ball clays. Another consequence is the need for an oxidizing firing atmosphere to prevent precipitation of carbon in the body during firing (soft porcelains often have an ivory-colored body, but the lower firing temperature allows a larger range of decorative colors).

A special type of soft porcelain is vitreous china. It contains distinct amounts of ball clays, which improves workability. Sanitary porcelains are a special type of vitreous china. They are designed for the fabrication of large pieces, which necessiates the partial use of ball clays and a single-firing technique. Sanitary articles are mostly formed by casting, which has to be considered when selecting the raw materials.

Bone china is the usual type of china for dinnerware and artware in the United Kingdom, but it is also produced in the United States, Scandinavia, and more recently in Germany. Its special features are high translucency, high whiteness, and good mechanical strength. The batch of bone china contains about 40 – 50 parts bone ash, 20 – 30 parts feldspars, and 20 – 30 parts clays. Because of the rather low clay content, workability of the crude body is more difficult than with other types of porcelains.

FritPorcelain. In frit porcelains, alkali-rich frits are used as flux, in combination with chalk and marls. Developed originally in 18th century Europe, they are used nowadays for buttons and costume pearls. Frit porcelains are self-glazing.

Dental Porcelain. The composition of dental porcelains is designed to develop high translucency. This is realized by batches with a feldspar content up to 70 % or even higher, together with some quartz and lime.

4.6. Porcelain Structure: Theoretical Background

The Kaolin – Feldspar – Quartz Phase Diagram. Kaolin, feldspar, and quartz are essential for the properties of triaxial porcelain bodies. The plastic kaolin promotes workability of the crude body. Feldspar acts as a flux, and allows full vitrification of the body at the selected firing temperature. Quartz ensures a reasonable drying behavior; it also controls the development of the structure (Gefüge) and thus the properties of the porcelain. During firing, it is dissolved and thus compensates the drop in viscosity during heating, by inreasing the silica content of the melt.

Porcelain bodies can be obtained only within a certain region of the kaolin – feldspar – quartz phase diagram (Fig. 3) [38]; the boundaries are 35 – 65 % kaolin, 20 – 40 % feldspar, and 0 – 45 % quartz.

Figure 3. Properties of bodies in the kaolin – feldspar – quartz sytem when fired to Seger Cone 14
Numbers indicate percentage porosity
D = dense structure, porcelain type; S = softened, slightly deformed; M = molten, F = friable, brittle

Reactions During Firing. The reactions in the kaolin – feldspar – quartz system are partly the reactions of the single components during heating, especially at low temperatures, before a molten phase has been formed; at higher temperatures, the components react with each other to form new phases [39, 40]. The reactions are described in detail elsewhere [41].

The reactions occurring in bone china bodies can be deduced from the calcium phosphate – anorthite – silica system (Fig. 4) [42]. Tricalcium phosphate and anorthite are found as crystalline phases in the fired body. Mullite and cristobalite do not occur, although stable according to the phase diagram; they react with impurities, e.g., alkaline oxides, forming a highly viscous melt, which solidifies as a glass during cooling [42].

The trapezoidal area to the right of center indicates the limits of the composition of bone chinas
Isotherms (— — —) are estimated (in °C)

Firing Atmosphere. It has been mentioned in Section 4.2 that hard porcelains are fired in a reducing atmosphere to develop a white color, whereas soft porcelains are fired under oxidizing conditions to avoid precipitation of carbon with its grey discoloration of the body. However, the reducing atmosphere for hard porcelain is also important to avoid secondary porosity which would result from partial reduction of trivalent iron at high temperature on release of gaseous oxygen.

4.7. Fabrication of China and Porcelain

(→ Ceramics, General Survey, Chap. 4.)

Body Preparation. The preferred preparation of china and porcelain bodies is wet ball milling. Costs can be reduced by using preground raw materials, so that body preparation

is reduced to homogenization in the ball mill. Sieving and magnetic removal of iron contamination from the equipment are standard practice. Further treatment depends on the intended forming process. Casting bodies are immediately deflocculated. Bodies for plastic forming are dewatered in a filter-press and homogenized in a deairing pug mill. Granulates for pressing are preferably obtained by spray-drying.

Dry preparation of china and porcelain bodies has not proved successful, because of the impossibility of removing iron contamination other than by passing the slurry over a magnetic separator.

Scrap from certain forming processes is redispersed, sieved, and added to the crude body. This not only saves raw material costs, but also improves plasticity and workability.

Forming Processes. For the fabrication of china and porcelain all the various forming methods in ceramics can be applied. Casting is used for hollow ware and complicated shapes. Pressure casting is tending to replace normal casting. Plastic forming of china is mainly executed with roller machines. Extrusion is a major process for technical porcelains. Isostatic pressing is increasingly applied for the production of tableware. Joining of component parts is executed in the "leather-hard" state.

Firing. Porcelain is usually fired twice, first at ca. 900 °C (biscuit firing) and then after applying the glaze at ca. 1250 °C (soft porcelain) or ca. 1400 °C (hard porcelain, glost firing). Glazing of the crude articles and single firing is commonly used for technical porcelain articles, especially when they are large. Attempts are being made to use single firing for tableware; dry-pressing and application of the glaze by spraying are promising fabrication steps to reach this goal.

The firing schedule of bone china and vitreous china is different: biscuit firing is executed at ca. 1250 °C and glost firing at ca. 1100 °C.

Tunnel kilns are used as well as shuttle kilns for firing chinas and porcelains; the trend is toward fast-firing kilns with a minimum of kiln furniture.

Hard porcelains are fired in a reducing atmosphere, soft porcelains under oxidizing conditions for reasons already discussed (Section 4.6).

Glazing. Glazes for hard and soft porcelains are normally transparent crude glazes. Frit glazes are used when glost firing is executed at low temperatures (bone china and vitreous china).

The Seger formula of the glazes has to be adapted to the body to adjust thermal expansion; the intended firing temperature is particularly important.

Glazes are applied to the ceramic body by dipping, pouring, or spraying. Automatic spraying equipment has also been introduced for tableware.

Processing After Firing. Further processes may follow firing, e.g., grinding and decoration.

Grinding and polishing is used to smooth areas free of glaze, e.g., saggar contact areas from which the glaze has been removed to avoid sticking. High-quality polishing avoids scratching of plates when they are stacked.

Articles for technical applications may be metallized or fitted with metal mountings, e.g., the shackles which are cemented onto certain types of electrical porcelain insulators.

Decoration (→ Ceramic Colorants). Decoration on china can be achieved by relief, color, and decorative patterns. Reliefs are applied during the forming process. Colors may be added to the body or to the glaze. Decorative patterns are applied to the unfired, biscuit-fired, or glazed body by painting, printing, or transfer techniques. Coating of the decoration with a glaze protects it from mechanical or chemical attack. Decoration applied to the glazed articles is fired under conditions where the glaze softens again; the decoration can sink into the glaze so that it is protected against attack.

The variety of color is greater the lower the firing temperature, but decoration fired at high temperature is more resistant to attack. The variety of colors capable of being fired at higher temperatures has been extended considerably by the introduction of the fast-firing technique and by the development of special pigments.

An essential requirement for decoration is resistance to attack by acids present in foods and beverages. They must not release toxic components such as lead or cadmium. A test with acetic acid is specified in consumer-protection standards.

Decorations can also consist of metallic patterns or ribbons of gold or platinum along the rim of plates or cups.

4.8. Standards

Requirements for porcelains used as electrical insulators are standardized in IEC 672. The standard comprises test methods and mechanical, thermal, electrical, and chemical minimum requirements for various types of materials. Porcelains form group C-100 of this standard.

European standards for articles in contact with food are presently in preparation. For tableware, standards on nomenclature and test methods for lead and cadmium release, water absorption, thermal shock resistance, translucency, crazing resistance, mechanical strength, and dishwashing resistance are being developed.

5. Technical Ceramics

From the wide range of technical ceramics classified as whitewares, two types are briefly considered here: steatite whitewares and cordierite whitewares.

Lithium aluminum silicates are also of technological interest because of their extremely low or even negative thermal expansion coefficients ensuring excellent thermal shock resistance. However, they have an extremely narrow range of firing temperatures when produced by ceramic fabrication procedures; they are preferably produced by crystallization of glasses, and so are better considered as glass ceramics (→ Glass Ceramics).

5.1. Steatite Whitewares (see also → Insulation, Electric, Chap. 3.1.2.2.)

Steatite whitewares are included in IEC 672 in group C-200 "materials based on magnesium silicates". Two types are important; type C-210, steatite, and type C-221, low-loss steatite. They differ in the kind of flux and thus in their properties.

Properties. Steatites have a dense structure with no water absorption, and a high mechanical strength approaching that of alumina porcelains.

Among the electrical properties, the low dielectric dissipation factor is remarkable, especially for low-loss steatite (type C-221) which is the preferred type in use.

Because of their thermal stability up to 1000 °C and their good electrical properties at elevated temperatures, steatites can also be used for insulating devices in electrical heating technology.

Among other properties, the high wear resistance is remarkable.

Fabrication. The main raw material is the steatite, the fine-grained variety of talc [$Mg_3Si_4O_{10}(OH)_2$]. Both types C-220 and C-221 are composed of ca. 85 % steatite, 5 – 10 % plastic clay, and 5 – 10 % flux (feldspar in steatite whitewares type C-220, and barium carbonate in low-loss steatites type C-221).

All common ceramic forming methods are used; the preferred method is dry pressing, because the excellent gliding properties of talc crystals aid compaction.

Steatite whitewares are fired at ca. 1300 °C, mainly in oxidizing atmospheres. For some applications, steatite components are coated with metal layers, preferably as a base for soldering them to other components.

Uses. Steatite components are widely used as electrical insulators, including high-temperature and high-frequency applications. Their use for high-voltage insulators of high mechanical strength has tended to disappear with the introduction of the alumina porcelains.

Steatite has a high wear resistance, hence the application for grinding balls and mill linings.

5.2. Cordierite Whitewares (see also → Insulation, Electric)

In IEC 672 two types of cordierite whitewares are standardized: C-410 dense cordierite and C-520 porous cordierite.

Properties. The main property of cordierite is its low thermal expansion, ca. $2\times10^{-6}\,K^{-1}$. This ensures very good thermal shock resistance.

Cordierite ceramics have a narrow range of firing temperatures. To mimimize fabrication problems, cordierite whitewares are preferably produced with a porous structure. This offers certain additional advantages: avoidance of fluxes in the body improves electrical resistance at all temperatures, the porous structure reduces the Young's modulus, and thermal shock resistance is further increased.

For certain applications, a vitrified type of cordierite whiteware is preferred. It can be obtained by the addition of flux to the body.

Fabrication. Natural supplies of cordierite are insufficient to meet the demand for cordierite whitewares. These are therefore produced from clay and steatite mineral in appropriate proportions. Fluxes are added when a dense structure is required. Feldspar has proved useful because it causes self-glazing of the body.

Production of cordierite whitewares follows the usual paths of ceramic fabrication technology. All forming methods can be applied, but extrusion has become the preferred method. Firing is at ca. 1300 °C.

No glaze is available with a thermal expansion coefficient lower than that of the cordierite body; self-glazing is a valuable characteristic.

Uses. Cordierite whitewares have been used for decades as insulators in electrical heating engineering because of the favorable combination of thermal and electrical properties. Cordierite components are used in huge quantities as catalyst supports for emission control; their excellent thermal shock resistance is the decisive property for this application. Dense cordierite whitewares are used for the production of oven-proof table- and kitchenware.

1. Introduction

Wind energy has become a recognized and proven form of regenerative energy generation, offering an environmentally friendly way to replace conventional, polluting energy sources in part (coal, petroleum, natural gas, nuclear energy). Depending on site or available subsidies, wind energy can now be put to economic use in many areas (especially the coast and coastal regions, as well as highlands). In contrast to conventional energy sources, wind energy inherently minimizes external cost arising from pollution damage to public health and disposal of toxic waste. The economic appraisal also includes cost for dismantling of the wind power plant after service life.

As wind energy utilization becomes more widespread, potential operators and other interested parties are confronted with general questions about the principles of wind energy technology. Detailed explanations of the overall topic of wind energy can be found in relevant literature. A comprehensive description of wind energy utilization is given in [7–9]. The discussion here provides an introduction plus brief explanations of some key concepts.

2. Power Content of Wind

2.1. Physical Power

Utilization of wind energy requires a knowledge of power contained in the wind:

$$P_{\mathrm{wind}} = \frac{1}{2} r\, \mathrm{v}^3 A \ (\mathrm{watts}) \tag{1}$$

where ρ is the density of the air, v is wind speed, and A is the cross-section of the area through which the wind flows. Whereas two of the quantities appearing in this formula, the air density and the wind speed are subject to changes in metereological conditions; the cross-sectional area can be arbitrarily chosen. The air density ρ is approximately 1.22 kg/m^3 at sea level, decreasing by ca. 10 % for every 1000 m of altitude above sea level. This naturally has an effect on the utilization of wind energy in the highlands and high mountains.

The effect of air density variation is slight in comparison to that of wind speed, since Equation (1) contains the cube of the latter. When the instantaneous wind speed increases by a factor of two, the power contained in the wind increases by a factor of eight. An increase in wind speed from 5 to 6 m/s results in a gain of ca. 70 % in the power content of wind.

For wind turbines, the reference cross-sectional area A is determined by the area swept

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_259

by the rotor. Doubling rotor blade length doubles the radius of the rotor circle and thus increases available wind power by a factor of four. Accordingly, the length of the rotor blades is a way of controlling the power that can be extracted from wind. As blade length increases, however, static and dynamic loads increase, and this must be considered in blade design, as well.

2.2. Efficiency

As with any energy source, one key criterion is how much of the primary energy can be converted to electrical energy. The rotor blade cross-sections of modern wind energy conversion (WEC) systems are shaped similarly to aircraft airfoils. In the usual operating range, these WEC airfoils generate aerodynamic lift forces that have a component in the rotational direction of the rotor. In theory, up to 60 % of the total power can be extracted from wind [1]. This value is referred to as the power coefficient c_p. The overall efficiency $c_\mathrm{p}\,\eta$ (η being the mechanical and electrical efficiency) is markedly lower because all components of a system contribute to power losses. Currently available $c_\mathrm{p}\,\eta$ values are ca. 40 – 45 %.

Wind energy conversion systems utilizing aerodynamic drag force are far less efficient. A panel set with its maximum area perpendicular to the wind direction will be subject to the aerodynamic drag force originating from the wind flow hitting the panel. The maximum power coefficient c_p for such a device is ca. 20 %. Because of the efficiency η of the machinery attached, even this 20 % is not actually achievable [7].

3. The Wind in Wind Energy

Earth's atmosphere is continuously exposed to the radiation of the Sun. About 2.5 % of solar energy is transformed into air currents (wind). The total power of all wind is around 4.3×10^{12} kW, although only a small fraction of this amount can be utilized [7]. Wind energy is a renewable energy source.

Wind is produced by local or large-area compensating movements of the air between regions receiving different amounts of solar warming or between regions of high and low atmospheric pressure. These compensating flows take place mainly near the ground. Air movements over land are much more attenuated than those over water because of the greater friction in the former. For this reason, wind over the sea has significantly higher speeds and weakens more slowly than wind over the land. In wind distribution maps, the coast and coastal regions normally have higher annual average wind speeds than inland regions.

3.1. Wind Maps

Because the energy content of wind is strongly dependent on its speed, an "isovent" map (a map with lines of constant wind speed) is often used to assess the potential of economical wind energy conversion.

Wind speed is determined in a variety of ways, for example, as 10-min average values or as annual average wind speed: 10-min and 1-h averages are calculated from measurements of wind speed at 1-s intervals. The 10-min averaging interval has become a standard and is used in most situations.

The yearly average wind speed is determined from the 10-min or 1-h averages over an entire year. A multiyear average is found by averaging over more than one year. The deviation from multiyear average is less than 0.2 m/s in ca. 50 % of years [10].

Although an isovent map gives a first indication of whether a region is suitable for wind energy conversion, it cannot be used in site selection because local conditions can differ greatly from plotted wind speeds. The yearly average wind speed depends on many factors; the most important are examined in the following sections.

3.2. Roughness

Wind describes the motion of air over the Earth's surface. Moving air loses speed through friction mainly in the boundary layer just above the Earth's surface. The degree of attenuation of wind speed at the surface strongly depends on the surface roughness. This roughness can be characterized by the roughness length z_0,

which is a normalization factor for the vertical wind speed profile in the boundary layer. The roughness length is much smaller than the actual dimensions of the roughness elements. The boundary-layer profile of wind speed v (Fig. 1) may be calculated with the formula:

$$\frac{\mathrm{v}_x}{\mathrm{v}_{\mathrm{hub}}} = \frac{\ln\,(h_x/z_0)}{\ln\,(h_{\mathrm{hub}}/z_0)} \tag{2}$$

where v_x is wind speed at height h_x and v_{hub} is the speed at the hub height h_{hub}. The smaller the roughness length z_0, the less is the wind slowed down in the boundary layer with decreasing height (Fig. 1). At very great heights above ground (ca. 1 – 3 km) wind speed is independent of the roughness of the terrain.

Figure 1. Boundary-layer profiles for various roughness lengths z_0.
Average wind speed is normalized to the value at hub level of 30 m (v_x/v_{hub}). Offset of boundary layer: 0 cm (according to [7], modified; source DEWI)

For shorter roughness lengths z_0 (i.e., over ice, water, or short-mowed grass), wind experiences less friction against Earth's surface. As the surface roughness increases (e.g., over unmowed meadow, stones, scrub, trees, buildings, woods, or built-up areas), wind speed declines near the surface. Typical roughness lengths (in meters) are given below:

Water or ice	0.0001
Mowed grass	0.01
Long grass or rocky surface	0.05
Suburban construction	0.6
Woods, city	1 – 5

In general, the wind grows stronger with increasing height above Earth's surface. On a large scale this effect creates opportunities for wind energy utilization in the highlands and high mountains. On a local scale, it makes tall towers for installation of wind energy conversion systems economically attractive. In addition, the friction of the wind against the surface depends on roughness: as roughness increases, the wind becomes weaker; making wind energy utilization economically doubtful in densely populated urban areas.

3.3. Frequency Distribution of Wind

One type of basic information needed to assess a potential site is annual average wind speed, but this alone tells nothing about fluctuations in wind speed and the frequency of light or hard winds. These variations, however, govern the amount of wind power available for conversion.

Theoretically, a yearly average wind speed of 6 m/s could mean that the wind blows at 6 m/s all of the time or that it has a speed of 0 m/s half of the time and 12 m/s the rest of the time, giving an average of 6 m/s. In the second case, the wind is four times more powerful because the formula for wind power contains the cube of the speed.

Information about the distribution of wind speed is obtained by measurement. Measured wind speeds are normally classified in classes 1 m/s wide and plotted as a frequency distribution (Fig. 2).

Figure 2. Typical frequency distribution of wind speed (according to [7], modified; source DEWI)

The experimentally determined distribution of wind speed is necessary because it is significant for determination of the expected energy yield. The distribution must be put in a suitable form before it can be used in energy calculations. Speed measurements can be modelled mathematically by the Weibull distribution:

$$f\,(\mathrm{v}) = \frac{C}{A}\left(\frac{\mathrm{v}}{A}\right)^{(C-1)} \mathrm{e}^{-\left(\frac{\mathrm{v}}{A}\right)^{c}} \tag{3}$$

where v is the wind speed, C is a form parameter ($1 < C < 3$), and A is a scale factor. The Rayleigh

Figure 3. Typical distribution of wind direction (according to [7], modified; source DEWI)

distribution, a special case of the Weibull distribution, may also be used when only the annual average wind speed is known for a site.

The wind speed distribution is also influenced by other phenomena such as diurnal variation of wind speed, calm periods, gusts, and turbulence. More information on these items is given in [10].

3.4. Wind Direction [11, 12]

Another property of wind to be considered is its variation in direction. Many institutions have conducted measurements over periods of years to establish a qualitative description of the changes in wind direction. The measurements show "preferred" wind directions, from which the wind blows more often and more strongly than from others. In Central Europe, the prevailing wind direction is southwest to west (Fig. 3); local deviations from this pattern are possible.

Selection of a good site for a wind power installation must take prevailing wind directions into account. Local conditions may cause the prevailing wind in a certain area to differ from the large-scale distribution of wind direction. Whether this difference is due to local obstructions, which could be avoided through choice of a better site, or whether it is a general topographic feature of the region must be ascertained.

4. Technology

4.1. Design of a WEC System

Figure 4 shows a horizontal-axis wind turbine. The schematic drawing includes only the essential components, some of which are not to scale for reasons of clarity. Not every WEC system has all the components shown; actual systems may differ from the one illustrated both in the components and in their exact position in the plant.

Some vital components of a wind energy conversion plant are explained in what follows: the basic design concepts of modern wind turbines, control systems, and generators. For other components such as yaw system, tower, safety systems, and the gear box, see [7].

4.2. Designs of Modern Turbines

Wind energy systems are designed either with a horizontal or vertical axis.

4.2.1. Horizontal-Axis Systems

Most horizontal-axis systems are wind turbines with one, two, or three blades. Several reasons exist for the use of rotors with few blades:

1) High rotor speeds, desirable for electricity generation, cut down gear box and generator costs.
2) Fewer blades lead to lower material costs.
3) Blade attachments for single-bladed and two-bladed rotors can be made in hinged form.

Three-Bladed Rotor. The three-bladed rotor (Fig. 5 A) is the most common type used in modern WEC systems. It represents a good compromise between the urge to minimize the number of blades and at the same time retain a simple dynamic behavior of the rotor. The mass distributions are so favorable that forced yaw motions of the rotor and nacelle are smooth and uniform. The rotor blades are usually attached to a rigid hub, which is inexpensive to produce, and requires little maintenance. All forces arising in the blade are transmitted to the hub, leading to severe loading on the attachment points and other mechanical parts of the machine. Three-bladed rotors run at lower speeds than two-bladed and single-bladed rotors of the same dimension. If they were to turn at the same speed as other rotor types, the blades would have to be narrower, which creates structural problems and is possible to only a limited extent.

Two-Bladed Rotor. The two-bladed rotor (Fig. 5 B) can operate at higher speeds, so gear box and generator costs are reduced. Because of the reduced size of the gear box and the reduced number of blades the nacelle and rotor mass is less than that of the three-bladed type. The two-bladed rotor, however, poses more complex aerodynamical problems than the three-bladed type. The change of the rotor's moment of inertia during one revolution may cause significant dynamic yawing and tilting loads that must be considered in the design of the system. The use of teetered hubs helps to control these problems.

Single-Bladed Rotor. The single-bladed rotor (Fig. 5 C) runs at even higher speeds than two- or three-bladed rotors can attain. The cost of gear box and generator is thus reduced further. The single-bladed rotor therefore has a lighter nacelle and rotor than systems with more blades. In addition to the dynamic forces that may occur in the two-bladed rotor, it has the drawback of unbalanced, rotating aerodynamic loads on the nacelle. The negative effects of these loads can be mitigated through proper choice of nacelle suspension and hub design. The higher speed of the rotor leads to a higher blade-tip speed for a given rotor diameter. High blade-tip speeds are associated with comparatively high noise emission from the turbine which must be taken into account in site selection.

4.2.2. Vertical-Axis Systems

At least for the present, vertical-axis wind turbines are of secondary importance. Their design follows one of two main trends. The *Savonius rotor* (not discussed further here) is a resistance-type rotor; it is used where the system must start at a low wind speed or where little power is required. Like horizontal-axis machines, the Darrieus rotor operates on airfoil lift forces.

Figure 5. Rotor design (source DEWI). A) Three-bladed rotor; B) Two-bladed rotor; C) Single-bladed rotor; D) Darrieus rotor; E) H-Darrieus rotor

Darrieus Rotor. The Darrieus rotor (Fig. 5 D) has the advantage of always "facing" the wind and thus requiring no yaw control. The generator and the control system are placed at ground level where they can be operated and maintained easily. The catenary-shaped rotor blades are easy to fabricate. Because the rotor is closer to the ground than in horizontal-axis systems, however, the energy yield is lower. These machines are more difficult to control and are generally not self-starting but require starting assistance.

H-Darrieus Rotor. Compared to the "conventional" Darrieus rotor, the H-configuration of the blades in the H-Darrieus rotor (Fig. 5 E) offers the advantage of still easier blade fabrication. The blades are located at a height compa-

rable to that of a horizontal-axis turbine, so the available energy yield is also comparable. Furthermore, power control (see Section 4.3) can be implemented in a similar way as with horizontal-axis rotors.

4.3. Power and Speed Control in WEC Systems

Wind energy conversion systems are designed to reach their rated power at wind speeds that are exceeded relatively frequently. To avoid excessive loading on mechanical or electrical components of a system when wind speeds exceed rated value (i.e., the wind speed at which the system delivers its rated power), precautions must be taken to limit the speed and/or the power output. Two principal types of control are used, both based on aerodynamical principles.

4.3.1. Stall Control

Passive flow separation along the rotor blade increases blade drag and reduces the driving lift forces. When operating below rated wind speed (partial-load operation), the flow pattern around the aerodynamically shaped cross-section of the rotor blade, which is mounted at a fixed pitch position, is optimal. If rotor speed is constant or nearly constant and wind speed increases, the local angle of attack (angle between the airfoil chord and the upstream flow) grows larger and larger until the flow separates from the airfoil surface; the process is similar to what is known as stall in aircraft applications. Flow separation reduces the lift and increases the drag. If the rotational speed must stay constant, the blade can be positioned such that the power output remains approximately constant above the rated wind speed. Often, power characteristics of stall systems show a drop in power above rated wind speed followed by a subsequent rise as wind speed increases.

The advantages of stall control lie in its simplicity and low cost. The disadvantages are high aerodynamic and mechanical loads on the components, the need for a dependable brake, and the comparably poor starting performance of the system after a period of standstill. This poor starting performance refers to the suboptimal fixed blade settings with respect to the flow conditions when the rotor is not yet operating at its nominal speed.

Stall control is found in all sizes of plants.

4.3.2. Pitch Control

Active blade pitch control alters the blade pitch angle continuously to control the lift force and hence the power extracted by the rotor. Pitch control permits easy starting of the rotor without auxiliary energy. Above rated wind speed and up to the "cutout speed" power extraction is controlled by adjusting the blade pitch to keep the output at the rated value.

Blade pitch control requires actuating equipment in the hub and thus higher costs than stall-controlled systems. For a proper design the forces acting on the rotor are generally lower than in stall machines. Pitch-controlled turbines are found in all sizes and are recommended wherever the power output of the WEC system must be deliberately controlled or should follow a prescribed value that is subject to changes.

4.4. Electrical Systems

4.4.1. Generators

Wind energy plants use essentially two types of generators, synchronous and asynchronous, together with their variants.

Synchronous generators offer high efficiency, do not require reactive power, and can be hooked up to the grid either directly or through an inverter (see Section 4.4.2). If connected directly, all power variations in the WEC system are transmitted to the grid without damping, so costly auxiliary devices are needed for synchronization with the grid.

Asynchronous generators are robust and require little maintenance. They permit easy synchronization with the grid but load the grid with reactive power demand. In comparison with synchronous types, they can be connected to the grid more softly. However they have a somewhat lower efficiency.

4.4.2. Operating Modes

Modern wind energy conversion systems are designed to generate electrical energy. They do so in three basic modes.

In the *island mode*, where the WEC system is the only or one of few electricity generating plants in a small grid synchronous or d. c. generators are commonly used. Grid frequency is governed by rotor speed, so turbine speed control is necessary to keep the grid frequency as stable as possible. The grid cannot always accept all the power produced, due to lack of power demand from connected consumers. Therefore, the system must be capable of partial-load operation (operation below the rated output). Conversely, if wind is lacking, the power demand may not be covered by the WEC so energy storage devices (batteries, hot-water reservoirs, etc.) or other energy sources (diesel generator, photovoltaic systems) must be included in the island network.

In *direct grid-coupled mode*, the rotor must turn at a virtually constant speed (with an asynchronous generator) or at constant speed (with a synchronous generator) and must have power output control. In a "strong" grid (where wind energy contributes a small fraction to power supply), all the power offered by the WEC is accepted; in a "weak" grid (large fraction of wind energy), all the power may not be accepted, again requiring controlled partial-load operation.

In the *indirect grid-coupled mode*, an inverter allows variable speed operation of the wind turbine; fluctuations in power output are greatly reduced, and grid coupling becomes very soft. The inverter first rectifies current from a synchronous generator that is variable in frequency and voltage; and then conditions it to the proper grid frequency and voltage. Important drawbacks of this arrangement are harmonics injected into the grid (whole-number multiples of the 50-Hz grid frequency), which must be suppressed with additional filters; losses of efficiency in the inverter; and additional costs due to the inverter itself. The potential advantage of this mode is its higher energy yield compared to directly coupled systems and the reduction of loads on the machine due to wind gusts.

5. Economic Aspects

This section examines the economic aspects of wind energy utilization from the viewpoint of a wind energy investor in Germany. However, the considerations apply in general. The economic analysis is based essentially on [13].

5.1. Factors in the Investment Decision

Capital Expenditure. Aside from the available energy yields, capital expenditure is the most important factor in the economic operation of a WEC system. Plant expenses can be expected to be dominant; additional expenses associated with the installation of the system along with plant expenses represent the amount carried as assets in the corporate balance sheet and written off over the economic life.

Even though a wind power system can be depreciated over 10 years, most manufacturers design their systems for an expected service life of 20 years. The key positions of capital expenditure are listed below:

1) Cost of plant ex works
2) Foundation costs (ca. 8 – 12 % of plant costs: pile foundation, flat footings)
3) Grid connection costs (ca. 8 – 12 % of plant costs: to low-, medium-, or high-voltage grid)
4) Connection costs by electric power utility
5) Site development costs (ca. 3 – 4 % of plant costs: access roads, data communications)
6) Transportation costs
7) Installation and commissioning
8) Planning costs (ca. 1 – 3 % of plant costs: building permit application, consulting, engineering inspection, notarial services, grading, expert opinion on topics such as noise, site, wind analysis, soil, and environmental safety)
9) Additional financing costs (bank consulting, interest for prefinancing of value-added tax, exchange premiums)
10) Land costs

5.2. Operating Expenses

Operating expenses are also an important factor in economic analysis. For wind power systems,

the items listed in the following are regarded as operating expenses (ca. 1 – 2.5 % of plant costs annually):

1) Costs of maintenance contracts
2) Insurance costs
   Liability insurance
   Machinery insurance
   Breakdown or operation interruption insurance
   Transport insurance
   Construction performance insurance
   Installation insurance
   Guarantee insurance
3) Energy costs (costs of energy purchased for operation of WEC system)
4) Tenancy costs

5.3. Factors Involved in Economic Analysis

Based on the discussion in the preceding sections, the starting parameters in economic analysis are as follows:

1) Reimbursement (in Germany 0.0866 €/kW · h, i.e., ca $ 0.1159/kW · h)
2) Grid-coupled operation
3) Company funds (ca. 10 – 15 % of WEC plant costs)
4) Additional costs (27 % of WEC plant costs)
5) Interest rate for costing (ca. 7 %)
6) Financing, interest, and amortization payments under market conditions
7) Power category of WEC system (500 kW)
8) WEC plant costs (1994 list price ca. 450 000 €)

Power characteristics taken from the manufacturers' product descriptions literature have been used to determine energy revenues for a reference site with various annual average wind speeds at a height of 10 m. Given a logarithmic wind profile and a roughness length of 0.05 m, the wind speed at hub height has been calculated by assuming a Rayleigh distribution. The long list of parameters shows that no general statement about individual WEC projects can be made within the scope of this brief analysis. Individual analyses are therefore indispensable.

Figure 6 shows energy generation costs (on the actual value principle) plotted against yearly average wind speed for 0 and 17 % subsidies, respectively.

Figure 6. Energy generation cost of wind energy converters (wind speed in hub height); rated power ca. 500 kW, rotor diameter ca. 40 m (according to [13])

Table 1. Present costs of wind energy, recalculated after [14]

Country	Costs per kilowatt-hour, $
Denmark [a]	0.05 – 0.07
Netherlands	0.07
Germany [b]	0.08 – 0.25
United Kingdom	0.09
Italy	0.10
Spain	0.11
Sweden	0.07
United States [c]	0.04 – 0.08

[a] Present information from [15].
[b] Cost history in 1994; range allows for differences in wind and financing conditions.
[c] Data from [16].

To determine energy generation costs per kilowatt-hour, projected interest rates, projected depreciation, and yearly operating costs have been considered. The most important parameters in the calculation are

Costs of the WEC system
Capital service
Operating costs
Energy yield

The last of these is the sole and decisive factor for the WEC system operator's receipts. The value depends on site selection, hub height, rotor diameter, efficiency, and availability. Information on planning, capital expenditure, and energy yield of different WEC systems is given in [9].

5.4. Present Cost of Wind Energy

Table 1 surveys the present costs of wind energy as presented at the 1993 European Community Wind Energy Conference in Travemünde (Germany) [7]; the information has been modified slightly, updated, and completed.

1. Introduction

Ralph E. Kunkee

Wine has been defined as “a beverage resulting from the fermentation by yeasts of the juice of the grape, with appropriate (and legal) processing and additions” [1]. This stark definition for wine becomes even starker when given in chemical terms: wine is an ethanolic solution of tartaric and malic and other organic acids, glycerol, phenolics, higher alcohols, sugars, and some 500 additional volatile and nonvolatile chemicals in trace amounts (see Chap. Chemical and Physical Composition of Wine). *Enology* (or oenology) is the study or science of wine and winemaking, while *viticulture* is the study or science of (wine) grape growing.

The rigid definitions for wine evade the distinctive and extraordinary position of wine in western civilization — in its history and culture. The literature on wine is enormous. It is estimated that more than 20 000 books and pamphlets, in various languages, dealing with wine or wine grapes have been published [1]. The library at the University of California, for instance, has nearly 5000 books with word “wine” in the title and receives nearly 500 periodicals having “wine” in the title. The vast interest reflects the giant intensity of devotion and adoration which the subject inspires — and also a disdain in some quarters.

Wine is not only an item of produce or a commodity, or perhaps a food or beverage (or even a health nostrum), but also has its mysterious, romantic, artistic and religious facets, which must not be ignored. These ephemeral facets become less ephemeral with the obvious recognition of the physiological effects of the alcohol (ethanol) in the wine — the ensuing euphoria of the partaker. Other alcoholic beverages have not brought forth the cadre of devotees as wine has. For example, the frequencies of the use in prose and poetry of words for various commodities and beverages shows wine to be an order of magnitude most prominent, with objects of art showing some approach to this.

Between the starkly chemical and physical characterizations of wine and the charismatic and enchanting features, the

subject of “quality” is also important: how good is the wine? or how bad? and how are these criteria established, if it all? Thus the topic of wine must to be presented on several layers, some of which are needed as in the usual descriptions of commodities, such as, for instance, cheese, or bread; others which might be applied to works of art; and then some layers, which are obviously unique to wine, embracing its charming and enigmatic attributes. Nevertheless, the emphasis of this keyword is on the physical and chemical components of wine.

[Top of Page]

2. Wine Classifications, Types, and Labels

Ralph E. Kunkee

A good and reasonable beginning in becoming acquainted with wine is an academic one — to become familiar with the various types or categories of wines, and to learn the associated vocabulary. In this approach, it is assumed that wines of each of the categories described are of “good quality”, leaving the difficulties associated with the words “quality” and “good quality” until later (see Chap. Sensory Evaluation). However, “bad quality” wine, whatever that is, does not mean dangerous wine. PASTEUR's counsel that “wine is the most healthy and hygienic of all beverages” [20] has stood the test of time and it still stands. That is, no human pathogen has ever been isolated from wine.

2.1. Major Categories of Wines

Several ways to categorize and subdivide the various classes of wines exist: In the following the system of AMERINE and SINGLETON is used [1], where the divisions are based, in order, on content of alcohol, dissolved gas, sugar, and then on color, and eventually on grape variety, geographical origin and age.

Also derived from fermentation of grape juice are other beverage products. Distilled spirits or brandies are described elsewhere (⟶ Spirits – Introduction, ⟶ Spirits – Wine Spirit. , ⟶ Spirits – Brandy, ⟶ Spirits – Cognac); dealcoholized wines are discussed in Section Dealcoholized Wines.

Table Wines Versus Dessert/Appetizer Wines. Employing the system just suggested [1] the first main division is based on the wine's content of ethanol [64-17-5]. Ethanol is the common end product of most yeast fermentations of sugars in all sorts of beverage and food fermentations. Those wines with lower amounts of ethanol, i.e., with ≤ 14 vol % are classed, in the English language, as “table wines”; because they are generally associated with consumption with meals. Those with a higher ethanol content (usually 16 to 20 vol %) are designated as “dessert/appetizer wines”. In several non-English languages, wines of lesser quality are commonly called something similar to “table wine”, such as: *vin de table*, *Tafelwein*, *vino da tavola*, etc. In the following the English term “table wine” is used, not pejoratively, but properly, even for the best wines. The wines with the higher ethanol content are usually consumed before or after meals, and thus are appropriately named either appetizer or dessert wines. Often these kinds of wines have special names, such as *vin doux natural*; the term “fortified” is sometimes been employed for these wines (see Section Dessert/Appetizer Wines).

The 14 vol % ethanol boundary is not arbitrary; it represents the limit of ethanol production possible by most strains of wine yeast under the usual conditions of grape juice vinification; although under other conditions, such as in saké making [21], these same yeast might produce as much as 20 to 21 vol % ethanol [22]. The 14 vol % limit is also operative in the storage and handling of wine. The higher concentrations of ethanol prevent oxidative spoilage by vinegar bacteria and further fermentation of sweet wines. Table wines ought to be consumed rather soon after they have been opened, as compared to the longer storage allowed for dessert/appetizer wines.

The 14 vol % ethanol boundary between the table and dessert/appetizer wines also has a regulatory and legal function: the collection of taxes. Under most governmental regimes, lower taxes, or none at all, are received from production and/or sales of wines with lower ethanol content. For example, in the United States, the federal taxes on table wines are $ 0.28 per liter and for dessert/appetizer wines $ 0.41 per liter. Furthermore most governmental regulations require that wines of any classification must contain at least 5 vol % ethanol. Some specialty wines may contain between 14 and 16 vol % ethanol [1]. Regulations on “dealcoholized” wines generally require that they contain < 0.5 vol % ethanol.

Of these two major wine categories, table wines represent by far the greater volume of wine production globally.

2.2. Table Wines

Divisions of table wines can be further based on color of the wine, grape variety, content of sugar, etc. Here the convenient system employed above [1] is used, basing the next major subdivission of the table wine category on the content of carbon dioxide [124-38-9]; that is, wines containing no evident amount (*still wines*) or those containing appreciable amounts of CO_2 under pressure (*sparkling wines*).

2.2.1. *Still Table Wines*

Governmental regulations usually allow still wines to contain a measurable quantity of carbon dioxide, but not enough to be obviously noticeable by sight or taste, which in effect means less than can be retained in the wine under standard pressure conditions (1 bar), i.e., less than 3.92 g CO_2 per liter. This category includes the largest volume and the most kinds of wine.

2.2.1.1. *Dry, Still Table Wines*

Dry is an enological term for wines having either no perceptible sweetness and/or wines containing no fermentable sugar (fermentable by wine yeast). Often these characterizations mean the same thing; but in this respect, yeast are more sensitive than humans. Wines which seem to been completely fermented to dryness by taste might in fact contain enough residual sugar to make the wine microbiologically unstable.

The dry table wines can then be easily further subdivided on basis of color: the words white, pink, and red are usually employed. In English, the French word *rosé* is often substituted for pink — where as in French, the word for black (*noir*) is used for red. Although these color descriptors are not exactly accurate (each of these categories has a wide range of hues, shades, and tints), usage has overcome the difficulties. That is, a green or yellow wine, of whatever intensity, is classified as white.

Dry, Still, Varietal Table Wines. This final categorization of table wines is based on grape variety, and indeed may supersede the classification based on color — since in almost all cases the grape variety dictates the wine color category. For example, wines made from Sauvignon blanc grapes are all classified as white, and those from Merlot as red. Although hundreds of grape varieties have been identified for production of wine, some thirty are commonly used. The geographical region often dictates the variety of grape to be used, and globally the regional names usually supersedes categorization by variety.

2.2.1.2. *Nondry, Still Table Wines*

The definitions of dryness are not precise (see Section Dry, Still Table Wines). To be microbiologically stable, the wine should be free of sugars which can be fermented by wine yeast. In fact that means that the residual concentrations of glucose [50-99-7] and fructose [57-48-7] should be zero or nearly so. In effect, wines fermented to dryness and considered “stable”, generally finish up devoid of glucose, but often with one to several grams per liter of residual fructose. These wines may also contain as much as 2 g of pentoses per liter, but pentoses are not fermented by wine yeast. For the consumer, the more operative definition of dryness in wine is the lack of perceptible sweetness. Again, that is not precise and will depend on the subject taster, the kind of wine, the setting, etc. Most experts assign 5 g/L glucose in wine as the sensory recognition threshold for sweetness.

In addition to wines with barely perceptible sweetness (as opposed to those not at all perceptibly sweet), wines with noticeable or obvious sweetness also exist.

Slightly sweet wines are often called *mellow wines*. These are often specialty wines, sometimes with proprietary names, but can be further classified by color and/or by variety. An important class of sweet wines are those produced from “late harvest” grapes, where the initial sugar concentration is so high that the fermentation is not completed and several percent of sugar remain in the wine. Usually these late harvest grapes develop the very high concentrations of sugar by a benign infection of “noble rot”. This rot, actually the fungus *Botrytis cinerea*, is dreadfully devastating except under the special conditions of late harvest. The infection allows for a gentle loss of water in the berries and thus an increase in the content in soluble solids, i.e., sugar. Furthermore this infection brings about excess formation of glycerol [56-81-5]. The subsequent inhibition of the alcoholic fermentation is due to the very high concentrations of sugar (which in itself is surprisingly inhibitory to yeast activity) and to the ethanol produced. The final products in these cases may contain only moderate amounts of ethanol, but because of the large amounts of sugar in the presence of ethanol, are microbiologically stable. The fungus attacks the acids in the berries, so the final acidity of the wine is normal. The fungus also seems to provide special fruit and honey-like flavors to the product. Wines in this classification are the Trockenbeerenauslesen of Germany and the Sauternes from Bordeaux.

2.2.2. ***Sparkling (Table) Wines***

Sparkling wines contain appreciable concentrations of carbon dioxide and are thus stored and packaged under pressure. By definition the term “sparkling wines” applies only to those wines wherein the excess carbon dioxide has come from yeast fermentation. However, wines to which carbon dioxide has been added artificially (carbonated wines), are sometimes included in this category. As far as is known only table wines are marketed with this excess gas, and thus to classify sparkling wines as table wines is probably superfluous.

The naming of sparkling wines, as a class, is highly controlled. Depending on country or region of origin and the procedure used in the production only certain terms may be employed, for example, *Champagne*, *cava*, or *fermented in this bottle*.

Dry and Sweet Sparkling Wines. Sparkling wines are rarely marketed completely dry. Some sweetness is required to balance the general high acidity in these wines, coming inherently from the base wine and also from the resident carbon dioxide (carbonic acid). In addition, the extra sweetness, in form of residual sugar, does not make these wines microbiologically unstable, because of the high acidity, high ethanol, and high carbon dioxide content. Apparently no standard agreement exists as to the labeling names used to indicate the sweetness, probably because the perception of it is so dependent on the other acidic attributes. However, AMERINE and SINGLETON [1] have provided a guide: 15, 25 to 45, 50 and 100 g/L sugar for *brut*, *sec*, *demi-sec*, and *doux*, respectively; even drier wines, with 6 g/L sugar, might be called *extra brut* [16].

The sparkling wines are subdivided on the basis of color as are the still table wines: white, pink, and red, although the categorization is not always as obvious as with the still wines. By far the greatest proportion of the sparkling wines fall in the “white” category; however, a large fraction of these are made starting with red grapes, so it is quite common to find them having a pinkish or bronze hue. Actual pink wines are also made. In addition, a small amount of red sparkling wines is produced. Red sparkling wines often have a manufacturing difficulty in that a rapid loss of carbon dioxide (gushing) occurs after opening of the bottle, probably due to particulate material arising from precipitated pigments.

As with the still wines, grape variety may be used to categorize these wines further. Again, the regional names may dictate the varieties and supplant the variety categorization.

2.3. Dessert/Appetizer Wines

A very conspicuous difference between table and dessert/appetizer wines, is that the latter are microbiologically stable in the presence of air (i.e., oxygen) and fermentable sugar (glucose and fructose). This is due to their higher content of ethanol, which has come about by addition of wine spirits, of “fortification” — the wine spirits being a distillate of wine, and often highly rectified, i.e., “silent spirits” with no congeners. The spirits must be distilled from wine, but depending on the

product, the wine distilled need not be of high quality, and indeed the distillation may represent an operation for salvaging ethanol from substandard wines. The fortification (*mutage*) can be made at the beginning of the fermentation; in the middle, “arresting” the fermentation; or at the end, depending on the kind of dessert/appetizer wine desired. This stabilization property of the fortified wines, as they are sometimes called, allows for the storage of them in open decanters at room temperature, for easy and spontaneous serving, whereas an opened bottle of table wine is susceptible to microbiological attack. Even so, there can be some problems with spoilages of the high ethanol wines, also.

Further categorizing of the high-ethanol wines is different from that of the table wines. Continuing with the preceding scheme [1], the dessert/appetizer wines will be divided into three groups: sweet wines, maderized wines, and flavored or specialty wines. The sweet dessert/appetizer wine category here is only for convenience, since sweet wines can also be found in the maderized wine and flavored wine categories.

2.3.1. *Sweet Dessert/Appetizer Wines*

In fact most of the dessert/appetizer wines are conspicuously sweet. As mentioned before, they are produced by addition of wine spirits, sometimes to grape juice which just begun alcoholic fermentation, or more usually after the ethanol concentration has reached several percent. However, in many cases the wines may be fermented to dryness and are then sweetened in conjunction with being fortified by spirits addition. The sweetening agents can be either conserved grape juice or fortified grape juice.

The nonflavored (see below) *white sweet wines* in this category are sometimes produced by the addition of wine spirits directly to grape juice that has only started to be fermented, or not fermented at all. The *mistelles* California Angelica, French Pineau des Charantes, and Ratafia de Champagne fall into this grouping. However, other white sweet dessert/appetizer may not be fortified until the fermentation has reached several percent of ethanol, examples are the White Ports of Portugal, the French Vins Doux Naturals and other Muscatels. *Pink sweek wines*, generally made by fortification well after the beginning of fermentation, might also include some wines with brownish hues. The most famous of the *red sweet wines* are the Portuguese Ruby, Vintage or Tawny Ports, but wines emulating these are also made elsewhere. These Port wines, especially the Vintage Ports, have the special attribute of improvement with age after being bottled; bottle bouquet otherwise generally found only in specially produced table wines.

2.3.2. *Maderized Wines*

The term maderized denotes those wines which have been intentionally oxidized by various methods to produce a characteristic flavor. For essentially all other kinds of wine, oxidation is an abhorrence — during production or in the flavor. Thus for these special wines, a term more appealing than “oxidation” is needed; the generic term “maderized” is derived from one famous group of this type from the Madeira Islands. This category is further subdivided on the basis of the procedure used in bringing about the maderization: film yeast, aging, or heat. The sweetness of the maderized wines is variable, they are thus considered as a separate category. All maderized wines should be classified as white wines; however, because of their production treatments they are generally dark in color, ranging from amber and tawny to very dark brown.

2.3.2.1. *Oxidized by Film Yeast*

The classic type of these wines are the flor Sherries from the Jerez region of southern Spain. Their complicated production involves the growth of film yeast (usually strains of *Torulaspora delbruekii*) on the top of the wine in partly filled barrels. The ethanol content must be high enough to prevent spoilage by vinegar bacteria, but low enough to allow these flor yeast to oxidize the ethanol and other alcohols. The *vins jeunes* of the Jura region of French are similarly made. Flor Sherries are naturally dry, because the flor yeast will not carry out oxidation in presence of glucose, but often they are subsequently adjusted to make them slightly sweet and with increased ethanol content. The flavors of these wines are complex but show little variation from year to year, due to a complicated fractional blending procedure, called in Jerez the solera system (solera coming from the Spanish word *sole*, or the ground, on which the lowest barrels of the system are placed).

2.3.2.2. *Oxidized with Age*

These wines are typically produced with enough ethanol to prevent any further microbial activity, while the wine is stored, again, in partly filled barrels. The classic type of these wines are the Olorosos of Jerez. These wines are of variable sweetness, sometimes coming from unfermented sugars of the juice, or from juice added after fortification. These wines also enjoy the benefits of the solera system. The special aging flavors in the these wines are produced before they are bottled. Only Port wines, among the dessert/appetizer wines, showing benefit from aging bottling.

2.3.2.3. *Oxidized by Heat Treatment*

These baked wines, the classic Madeira wines, are typically fermented as dry wines and then heated in open vats or tanks at ca. 60 °C for three to four months, and then sweetened and fortified. This style of treatment originates from wines that were shipped in the open on the open sea, where they were oxidized by the agitation and the heat from the sun. Some wines are still heated in the sun in glass containers, the process also being called a solera system — here the word is derived from Portuguese for sun. The system of sun heating of glass containers is also used for production of specialty wine in south western France, in Banyuls. The former California imitations of Madeira wines, the misnamed “baked sherries”, have now lost their popularity.

2.3.3. *Flavored Dessert Appetizer Wines*

This category is divided into two classes: the familiar Vermouths and the remaining specialty products.

2.3.3.1. *Vermouths*

These wines apparently had their origins as vermifuges, infusions of strange and flavorful botanicals in neutral wine spirits. Nowadays, the pretext for healing is gone, but wonderful, and sometimes secret mixtures of all sorts of aromatic herbs and spices are used, making the wines, even the sweet ones, popular as aperitives. The mixtures of herbs is so complex that

none of them is expected to be readily recognized. The infusions are generally made by the maceration of the herbs in fortified grape juice. The vermouths are often divided into two classes, the “French style” and the “Italian style”, having to do with their presumed geographical origin, not affinity. In comparison to the Italian style, the French vermouths tend to be of lighter color, not as heavily spiced, and are less sweet, having only a few percent sugar. Italian vermouths are much darker, sometimes almost reddish-brown, much sweeter (containing up 15 % sugar) and often with a noticeable bitter aftertaste.

2.3.3.2. *Specialty and Proprietary Dessert/Appetizer Wines*

An important class of dessert/appetizer wines are those to which particular herbs or flavors are added to give the product a distinctive, and often a proprietary, character. These wines usually have a definite flavor, which is, however, difficult to identify. These wines are generally not dry and often are quite sweet. A generic example would be sangrias of Spain, while brand names include French Dubonnet and Italian Campari. Some of the major firms producing these kinds of wines have started research programs to identify chemically the essences being used in these delightful concoctions, and also to search for biological activity associated with them.

2.4. Dealcoholized Wines

2.4.1. *Nonalcohol Wines*

The clientele for wines with lowered content of ethanol is continually increasing along with the modern emphasis on safer driving, diets with lowered calories, and increased health awareness. For whatever reasons, one factor has undoubtedly led to the increased appeal for dealcoholized wines: for many consumers, the new wines of this sort taste more and more like untampered wine. However, the removal of ethanol from the wine brings with it problems of microbiological stability. The stabilizing procedure of choice for protection of dealcoholized wine is sterile filtration and sterile bottling; but combinations of heat and addition of sulfur dioxide and sorbic acid, with any accompanying deleterious effects on flavor, are also used.

Three main dealcoholizing techniques are employed, each starting with table wines made in the usual way and of any of the categories given in Section Table Wines. Indeed, some producers commence with varietal wines of very high quality. The earliest dealcoholized procedure on a production scale employed the vacuum pan technology, which was developed for concentration of grape juice. For this, the liquid is put under a vacuum and the temperature raised to 30 – 40 °C, allowing the more volatile materials to distill off. For the grape juice concentrate the distillate is mostly water; but for wine, water and other low boiling fermentation products, and indeed most of the ethanol, is removed. More recently *reverse osmosis* (⟶ Membranes and Membrane Separation Processes – Principle of Reverse Osmosis) or *ultrafiltration techniques* (⟶ Membranes and Membrane Separation Processes – Principle of Ultrafiltration) have been employed, which probably are least violent to the product. The molecules with the lowest molecular mass, i.e., water and ethanol, migrate through the membrane leaving behind the other materials, including the volatile flavor components, in a small volume fraction of the original. The latter is then reconstituted with pure water approximately back to the original volume. A third method uses either *pervaporation* (⟶ Membranes and Membrane Separation Processes – Principle of Pervaporation) or *spinning cone technologies*, which are in effect very gentle adaptations of vacuum pan distillation. With these procedures, the wine is spread out into very thin surfaces, either by use of special membranes, or by a type of centrifugation, which under vacuum allows removal of some of the water and essentially all of the most volatile material, ethanol. Water is then added to bring the volume back to the original.

2.4.2. *Wines with Partial Removal of Ethanol*

Sometimes the final concentration of ethanol in table wines is higher than 14 vol %. Generally this situation arises from harvesting of overripe grapes, sometimes intentionally. Some winemakers are sure that with at least some grape varieties, greater ripeness brings with it more varietal flavor. In any case, excess ethanol can cause problems with imbalance in flavor and can also lead to excessive taxation. The methods described in Section Nonalcohol Wines, especially the ultrafiltration technology, have been well adapted commercially, to solve this problem. In these cases, only part of the ethanol and water are removed, usually to allow the final concentration of ethanol to be somewhat less than 14 vol %.

Ultrafiltration can also have commercial importance in the salvaging of wine with excessive volatile acidity, that is high concentration of *acetic acid* [64-19-7], arising from microbial spoilage (see Section Organic Acids and Carbonic Acid). Acetic acid is inhibitory to wine yeast (*Saccharomyces*) metabolism, and thus excess concentrations of it are not only objectional, in itself, but can be the cause of incomplete (“stuck”) fermentations. Acetic acid is a small molecule and thus can be removed by ultrafiltration. Treatment of the ultrafiltrate with ion exchange resin removes the acetic acid, and the deacidified material is returned to the main body of wine. The volatile acidity is removed, and in cases of incomplete fermentations, reinoculation with wine yeast should bring about dryness.

2.5. Wine Labeling

Understanding of wine labels can be the easiest or the most esoteric segment in learning about wines. Often, the word “wine” itself does not appear. Labeling of old world wines generally gives only minimal explicit information: the region where the grapes were grown, the year of the vintage, the final ethanol concentration (given on a percent by volume basis) and some indication of the quality (ordinary wine, first growth, etc.). To the uninformed, or the novice wine enthusiast, these labels can seem very mysterious and foreboding; but in fact, because of tradition and government regulations, the information on the old world label can imply much more: including the variety, or blend of varieties, of grape; the yield; the ripeness of the grape at harvest and the methods of production. In the new world (in the Americas, Australia/New Zealand and the Republic of South Africa) the labels usually explicitly tell more — but here again, the full disclosures may be lacking. For example, in California, the major grape variety used in the production may be divulged, but not necessarily how much of this variety was used, if it were not 100 %. Again, in California, the word “wine” may not appear if the grape variety and the concentration of ethanol is given; but if “wine” is used, then the concentration of ethanol need not appear. For all wines, the label will indicate the volume of the contents and the name and address of the producer; but again, these latter data may be deficient in explicit information.

2.5.1. *Importance of Region*

It is beyond the scope of this section to discuss the details of the wine labels of the world, or even of any definite regions. Competent guidebooks are available. However, a general rule can be given. For wines of higher quality, the grape growing location is of prime importance. The higher the quality of the grapes, and the wine produced from them, at least in some people's judgement, the narrower the delimitation of the vineyard region is likely to be. For example, a large region might be “France”, given wine of an ordinary type; while a very restricted location might be a vineyard in La Domaine de la Romanée-Conti in Burgundy, producing some of the most expensive wines of the world. In some regions much more than minimal information is given. For German wines, for instances, an indication of the harvest time and the ripeness of the grapes is implicitly given. Furthermore, many of the new world winemakers add more information than is required, often on their so-called back labels. In some regions further restrictive labels are required, supposedly for health or safety reasons; for example, the American requirement for “contains sulfites” labels.

2.5.2. *Controlled Appellations*

The sparseness of explicit information on the labels of high-quality wines gives them almost brand name status. Government regulations, local and international, have been instituted to protect the use of the prestigious, and often historical or folklorical names. Some sorts of controls of appellations of origin were put in place centuries ago, but the modern application begins with France's Appellation d'Origin Contrôlée in 1935. These regulations not only control the vineyard location and area, themselves being delimited not only on the basis of geographic but also political boundaries. They also include viticultural and enological considerations, as mentioned above. Although these restrictions have been initiated primarily for protection of the appellation and the property owners, and for the continued integrity of the product therefrom, they also provide a protection, a guarantee of product quality, for the clientele. These modern regulation systems had their origin in Europe, and they have been extended in some form to virtually all parts of the wine world. There seems to be no quarrel with the intention of these regulations, wherever enacted. However, neither the product nor its production or conception remain static. Thus, regulations such as these need occasional review and adjustment — which is very difficult to do, times after the fact. Many examples can be given where the appellation controls, unchanged for decades, are modern anachronims.

2.5.3. *Imitations*

Government regulations and international treaties can be strict to prevent expropriation of appellations of origin and other carefully guarded labeling characterizations. The most strict example is with the words: *Champagne* and *méthode champenoise*. International agreements limit the use of these labeling words to wines not only actually produced by the traditional method (fermented in this bottle), but also to wines produced by this method only in the Champagne districts of France. Thus, in most other regions of the world, the wine producers must name their product otherwise, e.g., “cava”, “spumante”, or “fermented in this bottle”. Sometimes the word champagne can be used elsewhere, but needs to be modified, such as “American Champagne”.

Several decades ago it was rather usual to find wines produced in the new world to be named after famous wine regions of the old — where the winemakers in developing wine districts, might be hoping to emulate the archetype wines, if not to fool their clientele. The terms Burgundy, Rhine, Sauterne, Rhône, etc., for these wines were more than common. This practice has practically disappeared, hopefully because the modern new world wine producers are endeavoring to set up their own standards and identities.

Some of the most misused appellation names and labels are imitations of dessert/appetizer wines with geographical identifications, such as Port, Madeira, and Sherry. Even in Spain in regions outside of Jerez, wines similar to Sherry wines are produced, for domestic consumption and for export. These cannot be called Sherry, so names reminiscent are used, such as “Solera”. For the wines of the new world such niceties are often ignored. Where enforcement of applicable treaties are not rigorous, the actual words, such as port and sherry are used.

[Top of Page]

3. Chemical and Physical Composition of Wine

Ralph E. Kunkee and Heinz R. Eschnauer

The main components of wine are water and ethanol. Important physical properties of such mixtures are described in Section Physical Characteristics. The components of next abundance are sugars, acids, other alcohols, and phenolics (see Section Organic Constituents) all being present in the magnitude of grams per liter, and as such are rather easy to be determined. These components are important in several aspects of the sensory qualities of the wine; in its sweetness or acidity, in its astringency or bitterness, in its mouthfeel (the viscosity or body), certainly in its color, and in its aging potential. Another group of wine constituents are volatile esters and acetals (see Section Esters and Other Aroma Substances). These occur in much lower concentrations and are much more difficult to assess; however, their evaluation is of preeminent importance, because they contribute to the odor and the taste, i.e., the vinous quality. Some other trace volatile compounds are explicitly identified with the aromas of individual grape varieties. Besides these, a very complex grouping of potential flavor components seem to be the glucosidic phenolics, which have operationally been named “flavor precursors” (see Section Polyphenols). In addition to all of these are the mineral components of wine, at various concentrations, and contributing various characteristics (see Section Inorganic Constituents).

3.1. Extract

The assessment of wine extract, a physical measurement, provides the enologist with indication of the chemical composition of the wine, and provides also information about how it was processed. Simply defined, the quantity of extract is a measure of the soluble solids in a wine after removal of ethanol and other volatile components [3]. Extract is composed mostly of glycerol and organic acids. Residual fermentable sugars, as dissolved solids, may or may not be included in the extract depending on the purposes of the measurements. Extract measurement may be helpful in assessment of sensory mouthfeel, and it can also be used in the detection of fraud. For example, illegal addition of sugar

to a limited volume of grape juice before fermentation would result in an excessive production of ethanol, which can be "corrected" by extension of the volume of the wine by addition of water. Flavor components are also diluted thereby and a sensory examination should detect this fraud; but if not, measurement of the improperly low extract value would.

3.2. Physical Characteristics

Wine shows, of course, all of the physical characteristics (densities, viscosities, surface tensions, and boiling points) associated with water – ethanol mixtures. The determination of the density of wine is about the only physical measurement routinely made, but this measurement is of paramount importance for the winemaker. Except for temperature, other physical measurements are almost never used or even made (see Section Temperature, Viscosity, Surface Tension and Tears); however, grape ripeness can also be determined refractometrically (see Section Refractive Index).

3.2.1. *Density*

Density measurements are performed not only on the wine and wine extract, but are also taken before, during, and after fermentation, to determine the fermentation behavior (see Chap. Alcoholic Fermentation). Densities are nominally given in grams per milliliter but several other scales are actually used by winemakers [3], depending on the country. Since the volume of a liquid is temperature dependent, the temperature of the wine needs to be determined as well when density measurements are made. The *Oechsle scale values* are derived from the multiplication by 1000 of the remainder of 1.000 subtracted from the specific gravity of wine; *Brix scale values* (and the closely related Balling values) give the soluble solids in wine in grams per 100 g (actually calibrated with sucrose as the soluble solid); and the *Baumé scale values* are calculated as the difference between 145 and the quotient of 145 divided by the specific gravity of wine [3]. Each of the scales is calibrated at 20 °C. Densities of wines, employing any of these scales, are measured with hydrometers. A hydrometer, in this case, is a weighted glass tube, constructed to float upright in the liquid to be measured, and in which has been placed the appropriate scale. The scale is calibrated so that the density, in whatever units, can be read directly, followed by a temperature correction.

The density of ethanol, under standard conditions, is 0.79 g/mL. Thus, the densities of table wines are usually lower than that of water, depending on the concentration of ethanol in the wine. The soluble solids in the extract (see Section Extract) will tend to increase the density. Thus a very dry table wine with 14 vol % ethanol and 2 % extract might have a density as low as 0.994 (–6 Oechsle; –1.5 Brix, –8.7 Baumé); while a Port wine with 18 vol % ethanol and 7 or 8 % of residual sugar might have a density of 1.024 (24 Oechsle; 6.1 Brix; 3.4 Baumé) [3], [23]. Density measurements are important in assessments of ripeness of grapes and of the course of grape juice fermentation.

3.2.2. *Temperature*

In addition to the density only the temperature of the wine is measured habitually by winemakers. The temperature is needed first of all to correct the density values. The temperature reading is also important for controlling both the alcoholic and the malolactic fermentations, but also to assure correct storage of the wine in the cellar and in bottles.

3.2.3. *Viscosity*

Viscosity of wine is very seldom determined, although it is often talked about by wine enthusiasts, especially in the context of its being correlated with sensory appraisals of the mouthfeel or the body of a wine. Wine has a higher viscosity than water (typically 1.5 mPa·s as compared to 1.0), due both to its content of ethanol (1.2 mPa·s) and of the extract materials (the viscosity of a 20 % sucrose solution is 1.96 mPa·s). The viscosity of water – ethanol solutions first increases with increasing concentration of ethanol, reaching a maximum of 2.89 mPa·s at 50 vol % ethanol, and then decreases to the value of pure ethanol. Viscosity can be sensed as a form of resistance when a solution is rinsed around the mouth, and thus seems to approximate what wine teasters call body [16]. Glycerol is a major component of wine extract, and thus it could be expected that enological practices which bring about higher concentrations of glycerol (application of selected yeast strains or fermentation temperatures) would increase both the measured and perceived values of viscosity. However, precise examinations of wines with high concentrations of added gylcerol, or of other viscous components, reveal no sensory detection of the increased material, even up to concentrations of 10 g/L glycerol [24], which is rarely found in wines, except possibly those made from *Botrytis* infected grapes (see Section Nondry, Still Table Wines).

3.2.4. *Surface Tension and Tears*

Again, surface tension forces are not readily measured in wine. However, a combination of surface forces of the wine and the forces of the interfacial tension between the wine and a wine glass result in the phenomenon of "tears", where the wine wets the glass, climbs up the glass surface, and eventually rolls back down to the liquid. Occurrence of tears seems to be related to the ethanol content of the wine. However, as pointed out in [16], evaporation of the wine and change in refractive index are also important, but not the viscosity.

3.2.5. *Refractive Index*

The refractive index is measured by winemakers to assess the ripeness of grapes at harvest time. Determination of the refractive index is perhaps even easier than the measurements of density and gives the content of sugar. The measured value is very sensitive to error in the presence of extraneous materials, especially ethanol. Thus, refractometric measurements are not used for following the process of fermentation, in contrast to density readings.

3.3. Chemical Composition

Chemical analysis of wine is an old branch of analytical chemistry. The quality of wine has undoubtedly improved with the application of analytical chemistry [25], although the understanding of the fermentation process itself, which preceded the chemistry [22], [25], surely played an equally important role. However, an understanding of the fermentation process would not have been possible without the continued improvement in the identification of the various wine constituents both qualitatively and quantitatively.

3.3.1. *Organic Constituents*

The major organic chemical components of wine are listed in Table 1. Some of the more interesting, well-studied, or unexpected components are discussed in the following sections. The listing in Table 1 has been gathered from several sources [3], [26-28], none of them very recent. The individual entries represent values from all classifications of wine and should be considered as estimates of orders of magnitudes rather than as precise measurements. For details on wine analyses, see [29-31].

Table 1. Organic constituents in wines

Carbohydrates	
Glucose	see text
Fructose	see text
Sucrose	see text
Pentoses	
Arabinose	0.8 – 2.0 mg/L
Rhamnose	0.5 – 1.0 mg/L
Ribose	0.04 mg/L
Xylose	0.2 – 0.4 mg/L
Galactose	0.13 mg/L
Mannose	0.04 mg/L
Fucose	0.005 mg/L
Pectin	trace
Inositol	0.3 – 0.5 mg/L
Alcohols	
Ethanol	see text
Methanol	0.1 – 0.2 mg/L
Fusel	see text
n-propanol	7 – 56 mg/L
Isobutanol	49 – 213 mg/L
Active primary amyl alcohol	111 – 193 mg/L
Isoamyl alcohol	627–773 mg/L
2-Phenethyl alcohol	5 – 74 mg/L
2,3-Butylene glycol	0.1 – 1.5 mg/L
Acetoin	0 – 0.03 mg/L
Glycerol	3 – 14 mg/L
Sorbitol	trace
Diacetyl	see text
Aldehydes	0.01 – 0.5 mg/L
Organic acids	
Tartaric	3 – 11 mg/L
Malic	1 – 6 mg/L
Citric	0 – 6 mg/L

* GAE=gallic acid equivalent.

3.3.1.1. *Carbohydrates*

Except for pectins, essentially all of the carbohydrates found in wine are sugars.

Sugars. The term *residual sugar* is most commonly applied to the sugars remaining at the end of the alcoholic fermentation. For dry table wines, the residual sugar is expected to be very low; but for all other wines the concentration of sugars may be quite high. Glucose and fructose are the natural sugars found in unfermented grape juice, and high concentrations of them will, of course, be found in wines which have not completed fermentation. Most wine yeast strains are glucophilic and ferment glucose faster than fructose; so that in table wines, near the end of the alcoholic fermentation, the glucose may be essentially gone, but the fructose might still be present in concentrations of 10 – 55 g/L [3]. Another complicating factor is that in many table wines, conserved grape juice (sweet reserve) or grape juice concentrate (see Section Sweet Dessert/Appetizer Wines), both having about equal concentrations of glucose and fructose, may have been added to provide sweetness. Still more complicating, in many locations sucrose is added at the beginning of the fermentation to provide for a higher concentration of ethanol (chaptalization). Some residue of sucrose may be present in the wine, although most of it would probably by utilized by the yeast or hydrolyzed to glucose and fructose by the high acidity of the grape juice. Sucrose is sometimes added in the form of caramel to provide color, and is used as the substrate for the secondary fermentations in sparkling wines. In addition, pentoses are present in the grape juice and remain in the wine (see Table 1), not being utilized by the wine yeast, at least under fermentative conditions. Thus “residual sugar” can have many different meanings.

The measurements of residual sugars and their interpretations depend on the analytic methodology used, which depends on the kind of sugar. With the exception of sucrose, all of the sugars mentioned above are *reducing sugars*, containing a terminal aldehyde, an α-hydroxyketone, or a hemiacetal group. These groups are easily oxidized, which is the basis of the common laboratory determination: reduction (although not stoichiometrically) of copper(II) sulfate [29]. A handy, portable method, based on this principle, are the copper(II) sulfate tablets (Clinitest), which are added to a tiny volume of wine,

giving a bright blue in the absence of reducing sugar.

In a sensory context, “dryness” means absence of perceptible sweetness, which for most individuals means less than 5 g/L of reducing sugar, easily evaluated with the Clinitest tablets.

Although “dryness” in wine is a subjective term, “dry wines with no fermentable sugar” (terminology very important to the cellar worker) normally contain some 2 g/L of pentoses, and when measured by these chemical means are designated as having 2 g/L of reducing sugars.

Values of reducing sugars higher than this indicate the presence of fermentable sugars. If the content of glucose is essentially zero, the small level of fructose contained (see above) probably does not affect microbial stability. Furthermore, some spoilage yeast (especially *Brettanomyces*) and some diacetyl-producing malolactic bacteria are thought to be inactivated only in stored wine which is completely free from glucose. The specific determination of glucose and of the other fermentation sugars is a little more involved. Potentiometric methods are available for selective measurement of glucose and/or fructose; and glucose, sucrose, and fructose can be determined by enzymatic methods. Clinical kits for home diagnoses of diabetes can determine glucose in blood confidentally at 100 mg/dL, and probably at one half at double that concentration. These procedures should be easily adaptable to enological needs.

The *pentoses* are not utilized by the wine yeast during the fermentation, but possibly may become carbon sources for the lactic acid bacteria which carry out the malolactic fermentation (see Section Malolactic Fermentation).

Pectins. Grape juice contains high concentrations of pectins, which consist mostly of polymeric chains of galacturonic acid and its methyl esters. Most of the pectins are precipitated during fermentation by the increasing concentrations of ethanol. Finished wines are often devoid of pectin, having been treated before or after the fermentation with pectinase enzymes.

3.3.1.2. *Aldehydes*

The last step in fermentative production of ethanol is the reduction of *acetaldehyde* [75-07-0] (which itself arises from decarboxylation of pyruvic acid). Acetaldehyde is highly reactive, binding with anthocyanin pigments and with added sulfur dioxide. It has a strong flavor, which is described as pungently nutty or as a raw pumpkin odor. Acetaldehyde should not be evident in properly produced table wines, but can be found in those which have not been protected from oxygen, either before the onset of fermentation or at the end of an overly long and protracted fermentation. Wines bottled without protection may also develop aldehydic flavors later from oxidation of ethanol. Wine enthusiasts are especially sensitive to wines showing any hints of oxidation; and when so, it is usually acetaldehyde that is noticed. However, in the various kinds of oxidized wines, i.e., sherries, madeiras, etc., acetaldehyde is the operative and the most desirable sensory constituent. In “submerged sherry” — which is produced by a suspension of yeast under a slight air overpressure to increase the oxygen concentration [3] rather than by a yeast film (see Section Oxidized by Film Yeast) — the concentration of acetaldehyde may reach as much as 1 g/L.

In addition to acetaldehyde, other low molecular mass aldehydes are present in wine. In maderized wines they probably contribute somewhat to the flavor and odor.

3.3.1.3. *Organic Acids and Carbonic Acid*

The two major organic acids associated with wine are L(+)-*tartaric acid* [87-69-4] and L(–)-*malic acid* [6915-15-7]. They are formed at about equal amounts in the grape berry, but as the berry becomes more and more ripe respiration of the malic acid occurs, which is more pronounced in warm climate. Thus at harvest, these two acids may be at nearly equal concentrations; or in very cold regions, the malic acid content may be substantially greater than that of the tartaric acid; and in very warm regions, the malic acid level may be reduced essentially to zero. Furthermore, in the wine the malic acid is biologically unstable. Here, a secondary fermentation by malolactic bacteria (see Section Malolactic Fermentation) often decarboxylates L(–)-malic acid to L(+)-lactic acid [79-33-4]. Thus the presence of lactic acid in wine primarily results from this fermentation, but can also arise from yeast and lactic acid bacteria metabolism of hexoses. Tartaric acid is essentially biologically stable, except toward attack by *Botrytis* in late harvested grapes (see Section Nondry, Still Table Wines). However, the concentration of tartaric acid is far from constant. Since pKa_1 of tartaric acid is 3.02 at the pH of grape juice and wine (generally between pH 3 and 4), most of the tartaric acid is in the form of its monopotassium salt, potassium bitartrate [868-14-4]. Potassium bitartrate is sparingly soluble in ethanol solutions. Thus most of the salt precipitates during fermentation, and much more of it is lost during cold storage. The latter operation is performed intentionally to stabilize the wine and prevent cloudiness whenever the bottled wine might be chilled.

Citric acid contributes less to the acidity of wine because it is present in low amounts.

The above acids are often equated with various flavors, such as fruity, lemony, milky sour, but in fact the pure acids all have the same characteristic acidic, but bland, flavor, although the intensities vary with the amount of acid (carboxyl) groups per molecule. Enologists refer to these acids collectively as *fixed acids*, in distinction to the *volatile acids*, such as acetic acid, given below. *Total acidity*, then, refers to the sum of the fixed and volatile acids, calculated as the nonionized acids. However, the term *titratable acidity* takes into account that these acids are partly dissociated at wine pH, that is part of the titratable protons of the total acid have been neutralized. For example, the p*Ka*'s of malic acid in wine are 3.45 and 5.33, respectively, and thus at a pH 3.4, a typical pH of wine, 52.5 % of the malic acid is not ionized, 46.9 % is present as hydrogenmalate, and 0.55 % as malate, and only the former two values are part of the titratable acidity.

Acetic acid [64-19-7] is a volatile acid, easily distilled off when wine is boiled. Titration of the distillate is the common procedure to determine the volatile acidity of wine, of which acetic acid is the major portion. Small concentrations of acetic acid are always present in wine, originating from the yeast fermentation, but a high concentration, distinctly above 0.5 g/L, is an indication of serious microbial spoilage. This most commonly arises from oxidation of ethanol by acetic acid bacteria, especially by the vinegar bacterium *Acetobacter aceti*, which therefore must be controlled by SO_2 and anaerobiosis

treatment. Anaerobiosis treatment requires periodic filling (topping) of developing head space (ullage) in wine barrels and addition of inert gas (N_2) to the head space of wine tanks. The indicated spoilage concentration of acetic acid is not easily sensorially detected, but is usually accompanied by another bacterial metabolism product, ethyl acetate [141-78-6], which is more difficult to measure, but which has a lower sensory threshold and is, in fact, the sensory attribute of vinegar. Small amounts of acetic acid are usually formed during the malolactic fermentation (see Section Malolactic Fermentation). Large amounts of acetic acid (5 g/L), which inhibit the wine yeast fermentation, are sometimes found in freshly crushed red grapes that are improperly stored before yeast or SO_2 treatment. These large amounts originate surprisingly from infection by lactic acid bacteria, not acetic acid bacteria.

Carbonic acid is hydrated carbon dioxide, which is of course one of major end products of alcoholic fermentation. Sparkling wines are produced under pressure and contain carbon dioxide under the pressure of several bars (see Section Sparkling (Table) Wines). Still wines are generally allowed to contain 3.92 g/L CO_2, the quality soluble under standard pressure, and young wines usually contain this amount. When the wine ages, the CO_2 dissipates. However, it is sometimes added back to certain wines, especially slightly sweet and fruity wines, at the legal concentrations, to add a fresh quality to the flavor.

3.3.1.4. *Alcohols*

Ethanol. Important physical characteristics of ethanol are discussed in Section Physical Characteristics. High concentrations of ethanol in wine may contribute a slight sweet taste and also give a slight burning sensation, described as hot.

Methanol [67-56-1] is not a direct fermentation product but may arise from demethylation of pectins (see Section Carbohydrates) by treatment of grape juice with pectinase. The concentrations of methanol may be considerably higher after distillation. Most countries have set legal limits of several grams per liter to the maximum concentration of methanol in brandies because of its oral lethal dose in humans of 320 mg/kg [29].

Fusel Alcohols. The higher alcohols, with higher boiling points and higher molecular masses than ethanol, are often called collectively fusel alcohols or fusel oil, because of their rank odor [3]. Generally, 2-phenethyl alcohol is not included with the fusel oil, on account of its low concentration and also because of it pleasant rose-like odor. Although the fusel alcohols represent a major fermentation constituent, their concentrations in wine are generally too low for them to play an important sensory role. However, their concentration increases during distillation which means they can be enriched in brandies. These alcohols are formed by the yeast during fermentation by decarboxylation and reduction of precursor α-oxocarboxylic acids. Isobutanol, for example, is formed from α-ketoisovaleric acid via isobutyraldehyde [3]. The α-oxocarboxylic acids themselves are part of the anabolic pathway of amino acid formation; in this case, α-ketoisovaleric acid is transaminated to valine. The higher alcohols can also be formed from their corresponding amino acids, using the same enzymatic pathways. Isobutanol, for example, is formed from valine (Ehrlich reaction) [3]. The final concentrations of these alcohols depend on several factors, including yeast strain, temperature, redox potential, and amine availability.

3.3.1.5. *Esters and Other Aroma Substances*

Some of the most well-studied *esters* contained in wine are listed in Table 1. These esters are present in wine in meager amounts, but because of their low sensory thresholds and their volatility, certainly contribute to the aroma of wines. However, they represent only a small portion of the total aroma perception. RAPP has indicated that the aromas can be separated into 600 – 800 single components, but also gives a table naming more than 1000 aroma substances [33]. It is beyond the scope of this keyword to go into detail, but aroma compounds in wine belong to the following groups of substances: hydrocarbons, alcohols, aldehydes, ketones, acids, esters, lactones, bases, organic sulfur compound, acetals, ethers, haloorganic compounds, nitriles, phenols, furans, epoxides, and anhydrides. The total content of these compounds amounts to about 1 g/L, or only 1 % of the ethanol concentration, and the fusel alcohols account for half of the aroma components. These components arise almost exclusively during the fermentation by the wine yeast, although the yeast strain itself seems to have little influence on the final sensory profile [3].

Grape Varietal Characterization. Considerable efforts have been made to correlate mixtures of various volatile components with specific and universally recognizable flavors. Just as important in this context is the discovery of aroma components of various varieties of grapes. Here, some progress has been made [3], [33]. The monoterpene alcohols (linalool, geraniol, nerol, citronellol and α-terpinene-4-ol) seem to define the muscat varieties such as Riesling and Gewürztraminer, and several 2-methoypyrazines (3-isobutyl-, 3-isopropyl- and 3-ethyl-) are responsible for the green pepper character of Cabernet Sauvignon and Sauvignon blanc varieties; Chardonnay contains vitispirane, 1,2,6-trimethyl-1,2-dihydronaphthalene, and damascenone.

Corkiness. One of the factors in the odor coming from defective corks, bringing out the “corked” sensory note in spoiled wines has been identified as 2,4,6-trichloroanisole. However, origin of this material, from the trees and their treatment, from the stored bark, from the bleaching and redyeing of the stamped corks or some other sources has not been established.

Bottle Bouquet. Storage of bottled wines over decades can bring about a highly prized maturity resulting in the development of a delectable aroma called bottle bouquet, variously described as the aroma from freshly cooked artichokes to that of freshly washed and air- and sun-dried bed linen. The conditions for attaining this special aging are not perfectly specified, and the compounds being developed are also not certain. However, again, some progress has been made: at least dimethyl sulfide and diethyl succinate have been implicated.

3.3.1.6. *Polyphenols*

Wine polyphenols consist of benzene rings usually with two vicinal hydroxyl groups, and include phenolic acids, cinnamates, flavonoids and tannins [3]. The kinds and amounts of polyphenols contained in a wine initially depend on

grape variety, especially on grape color. The following approximate distribution of polyphenols in wines is given [34]: hydroxycinnamates are in the range of 150 – 200 GAE/L (gallic acid equivalents per liter), while the anthocyanins and the polymeric tannins were found only in red wines at 200 – 400 and 600 – 900 GAE/L, respectively. The level of catechins and other monmeric flavonoids is low (25 GAE/L) in white wines but 150 – 200 GAE/L in reds.

The polyphenols and their reaction products form the basis of essentially all of the color, astringency, and much of the bitterness of wines. As a class, polyphenols are surprisingly reactive, if slowly so. They are the primary substrates for wine oxidation. The oxidation reactions are complicated, involving peroxy radical and hydrogen peroxide intermediates, resulting in among other things phenol dimers. Furthermore, the anthocyanins initially responsible for the red wine color are readily incorporated into phenolic polymers. Full understanding of these reactions, which can occur during storage after the wines have been bottled, will allow some prediction of changes in color and in astrigency of wines, and perhaps in the essence of bottle bouquet (see Section Esters and Other Aroma Substances).

Copigmentation. Although it is well-known that anthocyanins are responsible for the red color of wine, the reactions and equilibria involved are not completely understood. More pigment is held in solution than would normally be found based on solubility alone. The anthocyanins seem to form “stacks” in conjunction with other phenolics, and are considerably brighter in red color in solution than in the free form [35].

Flavor Precursors. It was mentioned above that perhaps more than 1000 volatile compounds are involved as flavor components of wine. New research suggests that there may be many thousands more. The polyphenols are generally glycosylated by α-bridges to two molecules of glucose, which renders them nonvolatile. New technology involves the hydrolysis of the glucoside bonds and the identification of the remaining volatile component [36]. It is supposed that these hydrolyses occur naturally and selectively during storage of wine, perhaps influenced by the pH. Rendered volatile, the components may act as odor and flavor substances. This could be specific for a grape variety, and also might involve enzymes of certain wine yeast strains and occur during fermentation.

3.3.1.7. *Nitrogenous Compounds*

The amounts and kinds of nitrogenous compounds in grape juice have the ultimate influence on the fermentations, especially by the wine yeast, but also by the wine bacteria. However, during the fermentations, most of the nitrogenous components are removed from the juice, and also from the wine when the microorganisms have settled and are separated [3]. The uptake of these components by the microorganisms has been studied intensively, especially the progression of uptake of the various amino acids, and the subsequent role this succession has on the rate and completeness of the yeast fermentation [3]. In the wine, problems with turbidity from proteins can arise after the fermentation, because the resulting ethanol brings about precipitation of the formerly soluble proteins. Although the precipitated fraction is small, it is sufficient to produce cosmetic problems unless stability operations are made. Increases in the level of small molecular mass nitrogenous materials, especially amino acids, does occur in wine with the practice of *sur lies*, that is, the storage of the wine on the yeast lees after alcoholic fermentation. Originally this practice was made just for this purpose, to increase the nutrients in the wine, and thus to stimulate the secondary bacterial fermentations, in cold regions of northern France, where the malolactic fermentation was difficult to induce because of the naturally low pH of these wines [3]. It is now practiced in other wine regions, especially in the new world, apparently to emulate the original product.

3.3.1.8. *Vitamins*

Similar to the nitrogenous components, most of the vitamins contained the grape juice are taken up by the yeast during fermentation. The results for vitamins found in wine given here are not recent, and ranges are from a wide assortment of wines, and are generally the results of microbiological assays. Nevertheless they give an indication of order of magnitude for some of the most important vitamins [26]:

Biotin	1 – 3.6 µg/L
Choline	17 – 41 mg/L
Inositol	220 – 730 mg/L
Nicotinic acid	990 – 2190 µg/L
Pantothenic acid	470 – 1870 µg/L
Pyridoxine	220 – 820 µg/L
Riboflavin	8 – 245 µg/L
Thiamin	2 – 58 µg/L
Cobalamine	0.0 – 0.16 µg/L.

3.3.2. ***Inorganic Constituents***

Approximately 1000 organic and inorganic constituents have so far been detected and determined in wine, of which ca. 50 are inorganic.

On careful evaporation of wine over a water bath, a syrup-like residue is formed. This extract consists of the nonvolatile inorganic and organic components of wine. Careful ashing (mineralization) of the extract gives the ash, which is composed of the nonvolatile inorganic constituents of wine, including the carbonates and oxides formed during ashing.

According to *definitionem vinum*, the inorganic constituents in wine are classified as mineral substances, with concentrations of up to 1000 mg/L, trace elements in the ppm range (ca. 1 mg/L or less), and ultra-trace elements (ppb range or ca. 1 µg/L).

Typical total concentrations per liter of wine are: mineral substances ≤ 5 g, trace elements < 50 mg (1 % of the mineral

substances), and ultra-trace elements ca. 50 µg (0.001 % of the mineral substances).

The ca. 50 inorganic constituents analytically determined in wine include eight mineral substances (four cations and four anions), ca. 25 trace elements, and ca. 20 ultra-trace elements, as well as rare earths and radioactive elements. About 500 articles have been published on this subject up to 1965 [37] and 20 – 30 new publications per annum have appeared since then.

A survey of the typical concentrations of the inorganic constituents in commercial wines is presented in Table 2, listed in order of decreasing concentration in the ppm and ppb ranges [38].

Table 2. Inorganic constituents in wine (typical normal concentrations in mg/L)

Mineral substances (1000 – 10)		Trace elements								Ultra-trace elements (≤ 0.001)

3.3.2.1. *Enological Trace Concentrations*

The total concentration of a trace or ultra-trace element in commercial wines (normal concentration) is made up of the primary concentration plus the secondary concentration. Generally, the total concentration is analyzed. Correct determination of the primary concentration is difficult and laborious since all steps from grape harvest to finished wine must be conducted completely free of contamination. The secondary concentration is important for evaluating impurities (“contamination”).

The primary concentration of a trace or ultra-trace element in wine is the natural concentration that enters the grapes and wine from the vineyard soil via the roots of the grapevine. This is generally the characteristic and larger part of the total concentration. The primary concentration often varies over a wide range because vineyards belong to various geological formations.

The secondary concentration of a trace or ultra-trace element refers to an impurity (“contamination”) of geogenic (natural) or anthropogenic (man-made) origin (Fig. 1). The known cases of contamination are listed in Table 3. An excessive secondary concentration is an indication not only of the cause, but also the extent of contamination [38].

Table 3. Secondary concentrations of trace elements in wine (contamination)

Figure 1. Secondary concentration of trace elements in wine

Natural contamination is of geogenic nature and practically unavoidable. It depends on the location of the vineyard. If grapevines grow near the sea or salt lakes, or close to active or extinct volcanos (exhalations), the wines obtained from these locations usually contain insignificant, but readily detectable, increased secondary concentrations of aluminum, arsenic, boron, bromine, chlorine, iron, gold, iodine, manganese, sodium, niobium, mercury, or zinc. These substances enter the finished wine via the grapes rather than through the roots.

Anthropogenic contamination, the true contamination of wine, can be caused in diverse ways, including industrial sites, enological contamination, or the addition of adulterating agents. It can almost always be prevented or at least largely reduced.

In wines from vineyards located near factories, steelworks, cement works, brickworks, coal-fired power stations, mining industries, highways, or cities, increased secondary concentrations of arsenic, lead, cadmium, boron, mercury, thallium (and fluorine on vine leaves) can be detected. Old (pre-1975) and younger wines from grapes grown near busy roads do not differ in their ultra-trace content of platinum (ca. 0.5 – 1.0 ppt = 0.0005 – 0.001 ppb). This cannot be said with certainty of the soil or the leaves, stems, and grapes of *Vitis vinifera* [39].

Enological contamination can be caused during winegrowing (fertilizers and pesticides), grape harvesting, and wine production (making of must and wine, storage, treatment, and transport of wine).

Contamination of wine cannot be excluded if crop-protection products that contain lead and cadmium impurities (137 – 1037 ppm Pb and 22.5 – 351 ppm Cd) are used. However, this contamination does not exceed the maximum values of 0.3 mg/L Pb and 0.01 mg/L Cd permitted by German wine regulations [40]. Until now, excess secondary concentrations due to crop-protection agents having Cu, Fe, Mn, Zn, or F, Cl, Br, or P formulations have not been detected. The average aluminum content of ecologically produced wines of 1.75 mg/L, which are treated with alaun-containing crop-protection agents, is more than 1 mg/L higher than the natural aluminum content of wine [41].

It is difficult to assess the possible transfer of trace elements to the vineyard soil by fertilizers (natural and artificial mineral fertilizer, manure, garbage compost, garbage sewage sludge compost, etc.). It results in hardly any or no secondary concentration in wine. In the case of *Vitis vinifera*, the heavy metal uptake from vineyard soil contaminated with artificial fertilizer and garbage sewage sludge fertilizer (outdoor experiments) by vine and grape components is very low. The uptake in must and wine is negligible. The vine roots act as a natural filter against heavy metals, especially lead and cadmium [42].

In grape harvesting, must production, wine preparation and wine storage, a range of materials are used, including nonferrous metals and alloys. As a result of corrosion and wear, excess secondary concentrations of antimony, arsenic, lead, cadmium, iron, manganese, silver, bismuth, zinc, tin, etc. can appear in wine. The rigorous use of high-grade steel and plastic results in trace-element free wines (e.g., 0.05 mg/L Pb and 0.5 µg/L Cd). On long-term storage, tanks made of stainless Cr – Ni steel can release slight traces of Cr and Ni, cement and concrete containers can release traces of Si and F, and glass-lined vessels and glass bottles can release traces of Si into wine.

Today, trace contamination of wine-treatment agents is the exception. Studies with model solutions and with wine show that contamination by these substances, which are frequently “natural” products such as bentonite, kieselguhr, lime, or activated carbon, is usually negligible.

A high secondary concentration in wine results from the deliberate addition of forbidden adulterating agents, usually in larger quantities, e.g., compounds of aluminum, antimony, barium, lead, bromine, boron, fluorine, manganese, strontium, or bismuth. These additions are intended to improve the wine via preservation, clarification, or correction of color, odor, and taste.

The enological topography of inorganic constituents can provide information not only on the distribution of primary concentrations over parts of the vine and grapes of *Vitis vinifera*, but also on a rare contamination of the grape skin. Trace impurities barely adhere to the smooth grape skins, which are covered by a thin wax coating, and can easily be washed off by rain. Thus, a distinction can be made between “external” and “internal” trace element content.

In element species analysis, the concentrations of elements can be defined according to chemical and physical states in a matrix. Statements can be made about the mobilizability, transport processes, plant availability, resorption, toxicity, etc. In enological element species analysis, wine can be regarded as the matrix.

Due to the large number and concentration of organic constituents in wine, element species analysis is more difficult and demanding than the trace analysis of the total concentration. Noninvasive and nondestructive analytical methods must be used to avoid disturbing the complex equilibrium in the wine sample.

In the case of calcium in wine, the magnitude of the element species stability ($E\text{-}St_{Ca}$) is used as a measure of the binding strength of the wine matrix. With this factor, a characterizing value for calcium stability in wine is obtained. Consequently, the storage stability of a wine with regard to calcium (crystalline deposits of tartrate salts) can be assessed after the determination of the calcium species stability [43].

Other element speciation results are available, e.g., for the trace elements aluminum [41], lead [44], copper, nickel, iron, and for the ultra-trace element bismuth. Bismuth is present in a water-soluble state in the flesh and juice of grapes, presumably ca. 90 % in the form of a complex with sugar acid [45].

3.3.2.2. *Metal Depletion in the Fermentation and Preparation of Wine*

The term depletion (dilution) refers to the decrease in concentration of mineral substances, trace elements, and ultra-trace elements during fermentation and preparation of wine. This depletion can be followed quantitatively and represented graphically and it can be element-specifically characterized by a depletion factor or the degree of depletion.

The fermentation of sugar to alcohol involves a natural depletion process for numerous metals, with a degree of depletion of up to 100 %. Little is known about how the metals are precipitated into the yeast sediment during fermentation. This occurs partly via sparingly soluble sulfides or hydroxides and partly by adsorption on suspended and turbid material. During fermentation and the subsequent steps leading to finished wine, metals are eliminated with various degrees of depletion. Cobalt, nickel, manganese, and zinc are eliminated at a low degree of depletion of up to 25 %; antimony, arsenic, iron, molybdenum, titanium, and tin at a moderate degree of ca. 50 %; while aluminum, lead, cadmium, copper, mercury, silver, and bismuth are eliminated to almost 100 %. Therefore, fermentation is an excellent natural self-purification process for many (toxic) heavy metals.

This purification process is supplemented by enological depletion via wine fining, wine casse, and wine sedimentation (crystals and “depot”).

In blue fining with potassium ferrocyanide (Möslinger fining), iron, cobalt, copper, and zinc are eliminated almost completely, and lead, cadmium, manganese, and vanadium are eliminated in considerable amounts as sparingly soluble metal ferrocyanides in the fining sediment.

Heavy metals can also be depleted in the filtration sediment by formation of metal turbidities, which appear at a threshold value of 10 mg/L Al, 5000 mg/L Zn, 3 mg/L Fe, 1 mg/L Sn, 500 mg/L Pb, 100 mg/L Ni, or 0.3 – 0.5 mg/L Cu, and in crystal deposits and the “depot” (insoluble settlings of old red wines).

The yeast, fining, and filtration sediments are separated as completely as possible from the pure wine. The clear filtered wine is completely or largely free of (toxic) heavy metals. It is the purest wine in the entire wine producing process. Any subsequent metal contamination is to be strictly avoided because a renewed elimination is possible, if at all, only with considerable effort and usually with a reduction in wine quality.

This contributed to the fact that strict maximum values for numerous metals in wine could be stipulated very early (Table 4) long before other environmental standards for beverages or foods.

Table 4. Maximum contents of trace elements (mg/L wine)

Element	Wine regulations * 1. 9. 1993	Drinking water regulations * 5. 12. 1990	Total content
Al	8	0.2	1

* Regulations in Germany.

Important characteristic data relevant to wine can be summarized in an element vinogram (for all mineral substances, trace elements, and ultra-trace elements). It contains, above all, element-specific and element-characteristic details about the concentrations in wine, including topography and speciation, about the secondary concentrations (contamination), about metal turbidity and depletion, etc.

3.3.2.3. *Enological Sample Bank*

Wines from earlier centuries can be used to compare trace elements in old and new wines. Trace analyses by modern methods allow incorrect results from older work to be eliminated. Old wines were previously almost never tested for trace elements or ultra-trace elements. In this evaluation, some uncertainty remains because the history of the sample bottle over long periods of time is not known to the last detail (refilling, recorking, storage conditions, etc.). Possible interactions between wine and glass must be taken into account.

Seven wines from the 1700s, 13 wines from the 1800s, and 37 wines from 1900 – 1950 have been tested for cadmium, lead, cobalt, copper, nickel, mercury, and zinc (Table 5).

Table 5. Concentration of trace elements in wine (average values in µg/L)

Period	Number	Cd	Pb	Co	Cu	Ni	Hg	Zn
1700s	7	4.56	2468	6.69	275	40.8	0.10	1340
1800s	13	3.66	4050	13.29	282	54.3	0.13	2040
1900 – 1950	37	2.53	602	6.25	746	87.7	0.17	2587
Modern wines		0.5	30 – 50	1 – 10	250	30 – 50	0.02 – 0.07	1500
Maximum values*		10	300		2000			5000

* According to German wine regulations.

The lead concentrations in wine have clearly decreased in the course of the last three centuries (factor ca. 100) to values of 0.05 mg/L today. The same applies to cadmium concentrations, which have decreased from 4 to 0.5 µg/L (factor ca. 10). These trends best demonstrate the development in wine producing techniques towards wines of increasing purity. A slight increase in nickel and chromium concentrations is observed, especially since the introduction of stainless Cr – Ni steels in the mid-1950s.

The increasing concentrations of the ultra-trace element mercury in wine was a trend for centuries. It was only in the 1970s

that it decreased rapidly with the widespread decrease in the use of mercury in industry and agriculture.

The measurement of ^{14}C and ^{3}H activities, which can be of natural or synthetic origin, also provides information on the wine year, vintage blend, falsification of the year, and addition of synthetic alcohol to wine.

3.3.2.4. *Essential Trace Elements in Wine*

In earlier times the health value of wine was held in high regard. Wine offers an abundance of mineral substances, trace elements, and ultra-trace elements in an especially favorable composition [46]. Two to three glasses of 1953 pure Ober-Ingelheimer late Burgundy contains largely the same type and amount of mineral substances and trace elements as two preparations of the pharmaceutical industry recommended especially for old and convalescent people[47].

The combination of a very high potassium concentration in wine with very low concentrations of sodium and chlorine is therapeutically interesting, especially in a low-salt diet.

Stress, a term introduced into medical terminology in 1936, can be prevented by the anti-stress minerals calcium and magnesium, which are both present in considerable amounts in wine.

Wine can contribute to meeting the human requirement of mineral substances and trace elements (Table 6).

Table 6. Essential trace element contents

	Recommended daily intake, mg	Wine, mg/L	Mineral water, mg/L	Milk, mg/L	Pharmaceutical preparation, mg/tablet
K	2000 – 5500	370 – 1120	3 – 663		
Na	1100 – 3300	7 – 15	2 – 2000		
Ca	800 – 1200	70 – 140	5 – 1044		37.6
Mg	350 – 400	60 – 140	2 – 536		5
Cr	0.05 – 0.2	0.03 – 0.06			
Co		0.001 – 0.02			
Fe	10 – 18	1	0.09 – 4.5	0.4	6.85

Sn		0.01 – 0.7			
Si		1.5 – 6	4.6 – 10.7		
V		0.06 – 0.26			

3.3.2.5. *Micronutrients for Vitis vinifera*

For the growth of grapevines, essential micro- or trace nutrients having potent growth factors are iron, zinc, boron, manganese, copper, and perhaps molybdenum. According to the minimum law of LIEBIG, any deficiency jeopardizes the effect of all the other nutritional and growth measures, even the yield and the quality of the grapes, produced by the macro- or primary nutrients [48].

Micronutrients are normally present in adequate amounts in the vineyard soil. If, however, depletion of the vineyard soil occurs due to the harvesting of grapes and this requirement can no longer be met, the vine suffers from acute nutritional disturbances. These can be remedied by suitable fertilizers containing trace nutrients.

Reports are frequently made about the favorable effects of (leaf) fertilization with salts of chromium, molybdenum, tungsten, etc. on vine growth, grape yield, wine quality, and even on wine preparation and ageing [49], without practical significance so far.

3.3.2.6. *Enological Trace Element Taxonometry*

In enological trace element taxonometry, the origin of a wine can be narrowed down and established from the primary concentrations (natural concentrations) of inorganic constituents by using monovariate selection methods (one element) or multivariate selection methods (several elements). If other selection criteria are to be combined, such as type of grapevine, year, and quality levels, the detection of multiple elements can be supplemented by additional data, such as organic constituents, organoleptic properties, or physical parameters.

Enological trace element taxonometry is a two-step process. In the first step, as many elements as possible are determined in multielement methods and, perhaps, other data of the wine are consulted. In the second step, all the data are used for group formation and selection in mathematical processes (discriminant, cluster, pattern analyses, etc.).

The idea of using the inorganic composition of must and wine to differentiate location and type of vine is not new. As early as 1939, the manganese concentration was used to differentiate French red wines obtained from European vines and from hybrid vines. However, a correlation of eight trace elements in soil and must determined by spectral analysis was not sufficient to identify the origin in 1961. In 1969, the determination of the location of Greek red wines grown near the sea was possible via sodium and chlorine.

According to more recent studies with multivariate selection processes of several elements, which are determined simultaneously with modern physical multielement methods, the geographical origin of wines can be classified according to the vine-growing land, vine-growing region, location of the vineyard, and soil formation. This classification is less suitable for the type of grapevine, year, quality level, or climate.

In the case of German wines, a distinction can be made between Alzey and Oppenheim in Rheinhessen, between Mosel and Rheinpfalz, and even between northern and southern Pfalz. In the latter case, it is possible to distinguish between Riesling and Müller-Thurgau wines. It is also possible to distinguish between Pinot noir wines grown in France and in the United States, and in the latter case, between the regions California and Northwest Pacific. In another study, a significant geographical classification was made of Bordeaux and Bourgogne wines as well as of French wines according to five different types of grapevine. Hungarian Riesling wines are differentiated according to three wine-growing areas. Italian red wines from Tuscany and four locations of Venetian white wines can be differentiated. The same applies to Spanish red wines from four Catalan wine-growing regions [50]. Some trace elements, such as manganese, iron, aluminum, alkali metals and alkaline earth metals, are especially suitable for identifying the geographical origin of wines.

Until now, a generally applicable method for the reliable determination of the origin of wine by enological trace element taxonometry has not been developed.

3.3.2.7. *Enological Isotopic Taxonometry*

If the abundance ratios of a series of standard wines are recorded in a data bank as an isotopic vinogram, the corresponding data of unknown wine samples can then be compared.

Enological isotopic taxonometry is an improved and supplementary process for enological trace element taxonometry. It allows the detection of wine adulteration by the addition of sugar (cane, beet, or liquid sugar), alcohol (fermentation and synthetic alcohol), water, and wine of lower quality, and incorrect labeling of the origin.

The radioactive isotopes in wine include natural geogenic ^{40}K, ^{87}Rb, U, and Th isotopes and daughter products of the U and Th decay series, anthropogenic isotropes ^{90}Sr, ^{134}Cs, ^{137}Cs, ^{226}Ra and other fission products from nuclear weapons (detectable, if at all, after Tschernobyl in 1987 and 1988 in grapes, must, and wine in concentrations far below EC limits), and the natural (atmosphere) and/or artificial (from nuclear tests) isotopes ^{3}H and ^{14}C.

Radioactive isotopes such as ^{3}H and ^{14}C are only of limited use in the determination of age and origin (after nuclear tests). The same applies to ^{137}Cs (after a reactor accident) for the determination of location.

The natural variations in the stable isotopes, especially of the light elements hydrogen, carbon, and oxygen, but also the heavy elements strontium and lead have proved to be very useful in solving many problems, such as the addition of sugar, alcohol, and water, the origin and blending, and the purity and contamination of wine. The following abundance ratios are used: D/H, $^{13}C/^{12}C$ [51], $^{18}O/^{16}O$ [52], $^{87}Sr/^{86}Sr$ [53], and $^{208, 207, 206}Pb/^{204}Pb$ [54]. The isotopes are determined by means of high-performance NMR spectroscopy and mass spectrometry.

3.3.2.8. *Enological Element Analysis*

The methods used up to the early 1970s were mainly colorimetry, spectrophotometry, gravimetry, and titrimetry. Since then, modern single-, oligo-, and multi-element methods have been predominantly applied in enological element analysis. With these methods, even the smallest concentrations of trace elements can be accurately determined.

In modern enological element analysis, a few instrumental processes of high detection efficiency and sensitivity dominate. Atomic absorption spectrometry (AAS) with its numerous variants (flame, graphite furnace, hydride and cold-vapor processes) is of great importance as a single-element method for a large number of trace and ultra-trace elements. Simultaneous multielement determination methods are being developed.

Frequently used oligo-element processes are based on electro-analysis. Differential pulse anodic stripping voltametry (DPASV) allows the determination of As, Bi, Cd, Co, Cu, Ni, Pb, Sb, Se, Tl, Zn (and Hg on gold wool).

Pb, Cd, Cu, Zn etc. can be directly determined in wine by means of potentiometric stripping analysis (PSA) [55], [56].

Multielement methods for simultaneous determination are wavelength and energy disperse X-ray fluorescence analysis and inductively coupled plasma atomic emission spectroscopy (ICP-AES), optical emission spectroscopy (ICP-OES), and mass spectromery (ICP-MS) with the highest sensitivity and possibility of isotopic separation.

Some special methods also find application for special problems in enological element, isotope, and speciation analysis [57].

[Top of Page]

4. Grapes and Grape Varieties

Ralph E. Kunkee

The grapevines from which wines are made are all members of the genus *Vitis* and belong to the botanical family Vitaceae. This family includes some ornamental vines, but no other food plants besides grapes [1]. The species *Vitis vinifera* makes up essentially all wine grapes of the world, the main exceptions being the species *V. labrusca* (perhaps a natural hybrid of *V. labrusca* and *V. vinifera* [58]) and *V. rotundifolia* (or *Muscadinia rotundifolia* [58]), both native to North America. These latter two species have intense, if not highly regarded, non-*vinifera* odors and flavors; their use for winemaking is generally confined to their geographical origins. Koshu is the native non-*vinifera* variety of Japan, and there are other Asian non-*vinifera* varieties. Some winemaking is also based on hybrid vines from genetic crossings of *vinifera* and non-*vinifera* parents, whereby some of the disease resistance of the non-*vinifera* parent, is inherited but these are also not important in the global wine picture. The discussion here is devoted to *V. vinifera*, often referred to as the wine grape or the European grape, since the vast quantity of the world's wine is produced in Europe from this grape. However, the vine's origin seems to be, rather, more Middle Eastern, perhaps near modern-day Iraq [1]. (Some authorities divide the *Vitis* genus into two subgenera, *Euvitis* and *Muscadiniae* [59], the latter including only some North American species and the *Euvitis* being subdivided into North American and Eurasian species, in which *vinifera* is placed [59]. However, the single genus *Vitis* is used here).

4.1. *Vitis vinifera* Varieties

The “wine grape” (*Vitis vinifera*) does not tolerate extreme climatic conditions, and its growth is limited to the temperate zones, 30 – 50° N and 30 – 40° S, (10 – 20 °C isotherms) [58], [60].

The varieties are simply divided into “white” and “red” grapes. White varieties range in color from light green to dark yellow, and the red ones from pink to deep purple or black, the degree or depth of color being highly dependent upon cultural conditions.

There are some 15 000 named sub-species (cultivars or varities) of *V. vinifera*, but probably only 1000 have been exploited for wine production, and of these, perhaps only a few dozen are actually in use commercially. The varieties are often identified with famous old-world wine regions, the appellations thereof indicating the varieties. Some of the most important *V. vinifera* varieties are listed here, indicating those of greatest global planting (*) [1], [3], [16], [59-61]:

Airén*
Aligoté
Aramon
Barbera*
Black Malvoisie
Boal
Bobal *
Brunello
Bual

Viognier
Viura
Walschriesling*
Xarel-lo*
Zinfandel

Longer lists can be found in [1], [3] and more-or-less complete compendia are given in the amelographies of GALET [61] and MORTON [62].

Worldwide use of *V. vinifera* is not limited to wine production; the grapes are also used as fresh table fruit and dried for raisins. The relative proportions depend upon the market value of the three commodities, religious prohibitions against wine and brandy, and seasonal and transport considerations.

V. vinifera in Winemaking. The most prominent attribute of *V. vinifera* — besides the properties of its juice which allow the production of a beverage of high ethanol content and high acidity, giving wine its microbiological stability — is that the product does not have overstated flavors, but rather a subtlety that allows the flavors to remain unobtrusive.

The tannin and anthocyanin pigments (see Chap. Chemical and Physical Composition of Wine), which provide the red color and astringent and bitter flavors to wines are highly localized in the skin of *V. vinifera*. For red wine production these elements must be extracted, which is generally done by fermenting these grapes “on the skins”, the heat and ethanol releasing them from the skin cells. For white wine production from white grapes, the skins are generally removed before fermentation, to decrease the bitter and astringent components. White wines can also be made from red grapes by complete and careful removal of the skins before the onset of fermentation. Some two-thirds of Champagne production is from Pinot noir, a red grape. In all cases, extraction of the very harsh tannic materials from the grape seeds is to be avoided, preferably by early removal or by preventing crushing of the seeds.

V. vinifera Identification. Until recently, precise varietal identification has been extremely difficult because of large phenotypic variations caused by environmental factors and cultural practices. However, DNA profiling methods have begun to clarify some of the historical varietal confusion [63]. Varieties can be further subdivided into clones. Clonal selections can be made from examination of vines in sections of vineyards containing a single variety, noting the variations thereof, and then making vegetative, rather than cross-breeding, propagations of vines with superior characteristics. The DNA profiling methods used to date do not generally detect clonal differences, but there is hope that more sensitive genetic techniques will eventually allow the identification of clones [64].

4.2. Rootstocks

The major disadvantage of *V. vinifera* varieties is their susceptibility to various diseases, (see Section Grapevine Diseases), mainly originating from the new world, and including especially the root-sucking aphid Phylloxera, commonly called the root louse, but more accurately *Dactylasphaera vitifoliae* [16], [58], [65]. This insect, literally sucking the plant to death, caused devastation of European vineyards, especially in France, starting in 1863, with reoccurrences from time to time, in France in the 1910 s, and currently in California. The life cycle of the aphid and its relationship to the grapevine's roots are complex. Currently the only definite antidote is to graft the desired variety of *V. vinifera* (as the top part, or scion) onto a rootstock (bottom part), which is completely free from any *vinifera* parentage. The most successfull rootstocks are those having evolutionary resistance to the pest, that is, *Vitis* species originating in North America, such as varieties of *V. riparia* and *V. rupestris*, and hybrids thereof. The modern phylloxera problem, especially in California, is further complicated by the appearance of a new form of the insect, the so-called biotype B [65].

Nematode roundworms are another form of vineyard devastation. They also attack the roots of the vine. Not only do they bring about root damage, they can also act as virus transmittters, or vectors. The solution to nematode damage is not as developed as that for phylloxera. The roots of some non-*vinifera* species (*V. solin* and *V. champini*) show resistance and some chemicals are helpful in control [16], [58].

[Top of Page]

5. Viticulture

Ralph E. Kunkee

Viticulture, the science of grape growing, is very complex, both because of the great global variations in its culture, and because of the complexity of the grapevine itself. Its importance cannot be overstated; it is truly said that the production of great wines starts in the vineyard.

Commonalities in these considerations are the dormancy stages of the annual growth cycles of *V. vinifera* and how these are utilized by vineyardists and the importance of the agreement of grape variety with the *terroir*, the total natural environment of the region, including soil and climate.

5.1. Dormancy and Its Utilization

The dormancy period of *V. vinifera* occurs with the beginning of winter's short days and cold temperatures [58]. (In fact, in warm or equatorial regions, such as India and Venezuela, there are no natural dormant periods, and dormancy must be induced by heavy pruning of the vegetative growth.) During the dormant period, the viticulturalist has the opportunity to prune parts of the dormant wood. This is done first to control the number of buds to be left on each vine, which dictates the number of new shoots and potential clusters, and berries, and thus the size of the next harvest. Equally important, the dormant period allows the shaping, the type of trellising, or canopy management of the new growth coming after “bud break”, that is, after the reversal of dormancy with the advent of spring.

Crop Size. The extent of dormant wood removal and the number of buds to be retained is an important decision of the vineyard manager, as this influences the next crop size. The crop size, the weight of berries produced per vine, is generally considered to have a profound effect on the quality of the wine produced. The arguments are first, that a vine can only support so much crop, and if “overcropped” the berries will not ripen sufficiently; and second, small yields (“undercropping”) tend to produce larger berries, with lower surface area to volume ratios – the color and flavors being concentrated in the berry skins.

Interestingly, in Australia, where pruning labor costs are relatively high, there is a new proclivity for minimal or no pruning [16]. The expectations seem to be that after a few years, the grapevines, left to themselves, adjust and bring into balance crops which are large enough and with berries small enough to warrant this “benign neglect”.

Canopy Management. The last few years have seen new interest in shaping and trellising systems, the positioning of buds and the pruning of the new growth after dormancy — all coming under the term canopy management [69]. The main idea is to manipulate the areas and positions of the leaves of the grapevine in relation to the sunlight (and wind and rain), to engage the best aspects of region's soil and climate, bringing about the full potential of the vine in producing its healthiest and heaviest crop, while at the same time giving a crop fully ripened and with full distinct varietal flavor [66].

5.2. Agreement between *Terroir*, Climate and Grape Variety

Terroir is the French word for soil, but for the viticulturalist, the word has come to mean more than just the composition and structure of the earth of the vineyard, or of its drainage and layout, etc., and generally includes the total natural environment of the region, and often the climate [16]. In vineyard site selection, regardless of the canopy management to be employed, all aspects of *terroir* ought to be considered.

There are two schools of thought on the importance of *terroir*, in its original, narrow definijtion, as compared to the importance of climate in the production of high-quality wine. Arguments on the one side have been that grapes from adjacent vineyards with two types of soil often produce two types of wine in the same climatic year. Nevertheless, only recently have actual studies and comparisons of compositions and structures of soils from designated vineyard sites been made. [67]. Arguments on the other side have been that grapes from a single vineyard often produce varying kinds of wine from year to year, obviously due to variations in climate, not in the soil.

Viticulturalists in old world wine regions have not given great importance to the role of climate in vineyard designations, since the establishment of appellations and their proper varieties have been historical and evolutionary actualities. Trial and error and production of high- and low-quality wines over many centuries dictated success. In the new world wine regions, this long experience is not available; it has been necessary to provide some sorts of climate classifications. One of the most successful has been the California heat summation system, where the vineyard regions have been divided into five climatic zones, depending on the product of number of days with temperatures greater than 10 °C multiplied by the differences in actual temperatures and 10 °C for those days [26].

Modern viticulturists see the importance of the total concept of *terroir*, in order to provide the winemaker with grapes which have their full potential, free from disease and expressing all of their varietal distinctiveness.

5.3. Grapevine Diseases

V. vinifera grapevines are susceptible to many pests besides phylloxera and nematodes (see Section Rootstocks). MULLINS et al. [58] list — and give symptoms and control measures for — six fungal diseases of the leaves and fruit, four fungal diseases of the vascular system, three bacterial diseases, three viral diseases, and one miscellaneous disease. *Botrytis cinerea* devastation is a global vineyard problem, often named “bunch rot” or “gray rot”. This fungus does not require accidental lesion of the berry skin for infection, as do many other fungi. *B. cinerea* is only the fungus which aids in production of the highly acclaimed “late harvest” wines (see Chap. Wine Classifications, Types, and Labels), and is in that case named “noble rot”. Some microbial infections depend on weather conditions and some on cultural practices. For example, downy mildew fungus (*Plasmopara viticola*) is generally found in regions of summer rainfall; the bacterial infection of Pierce's disease (*Xylella fastidiosa*) is found near the riparian habitats of its insect vector, a leaf hopper. The fungi producing powdery mildew (*Uncinula necator*) and black rot (*Guignardia bidwellii*) both originated in the new world; and arrived in Europe (last century) to start, and then to finish off, respectively, the devastation from the co-immigrant Phylloxera.

The other listed diseases [58] can be just as destructive as the ones especially mentioned here.

5.4. Other Viticultural Practices

For further information on viticultural practices, not discussed here, such as the use and roles of irrigation, fertilization, integrated pest management, grapevine biology, physiology and anatomy, etc., see [3], [16], [58], [68].

[Top of Page]

6. Alcoholic Fermentation

Ralph E. Kunkee

“Must” is the enologic term for grape juice which is ready for fermentation. For white wine production, must usually refers to juice, without skins and seeds. It can also refer to crushed grapes, that is, the juice, skins and seeds, which is normal for red wine production. Alcoholic fermentation is fermentation of the grape sugars to ethanol and carbon dioxide by wine yeast. Malolactic fermentation by wine bacteria is discussed under secondary fermentations (Section Malolactic Fermentation).

6.1. Pre-fermentation Operations

Harvest. For best quality of wine, the grapes should be ripe enough that the sugars are adequate to ensure the high concentration of ethanol desired, but not so overripe that the acidity is too low (i.e., that too much of the malic acid in the berry has been respired). Much of the world's wine grape harvest is done mechanically, which from a quality standpoint has several advantages: more precise scheduling of harvest because of the smaller labor force needed and in warm regions, the capability of harvesting in the coolness of the night. The main disadvantages, and they are important ones, are that the juice is prematurely exposed to air and the oxidation problems which this brings and that the rough treatment of the skins is more likely to allow extraction of harsh and bitter materials (see Section Polyphenols) [3].

Crushing and Stemming. Often crushing and (de)stemming are performed by the same of equipment. The stems are removed since, like the seeds, they can add harsh flavor. Also it is important that all of the grapes be broken open so that the yeast will have contact with the juice for fermentation [3]. There is increasing interest in mild crushing operations that avoid introduction of harsh tannic materials. Furthermore, the idea of “whole berry” fermentations has some adherents, that the presence of unbroken berries, at least until near the end of the fermentation, provides some special flavors. The ultimate in this concept is so-called “carbonic maceration” [3]. In this operation, most of the berries are not crushed, but completely immersed in carbon dioxide gas. At somewhat elevated temperatures, the berry enzymes begin fermentation of the sugars to ethanol. Eventually, the grapes are broken open and the fermentation is finished in the normal way. This gives a special flavor and provides wines ready for bottling much sooner [3]. This process is associated with the wines of Beaujolais, marketed as early as November as Premeur wines.

Sulfur Dioxide Addition. Sulfur dioxide is universally used in wine production, both to inhibit oxidation reactions and as an antiseptic [3]. The latter activity is important to inhibit indigenous yeast and bacteria, especially when a yeast starter culture is not used or if the grapes are infected with rot. Sulfur dioxide is a slow scavenger of oxygen but shows rapid anti-oxidation activity in the inhibition of polyphenol oxidases of the must, which can cause severe browning. Since much of the oxidized phenols become further polymerized, these brown pigments precipitate. Winemakers nowadays are careful to use low concentrations of sulfur dioxide for this gentle method of removing browning. Sulfur dioxide is also added during the storage of wine, for its antiseptic and anti-browning activities, and generally just before the wine is bottled. Sulfur dioxide has some objectionable qualities in regard to flavor, and perhaps to health, and thus needs to be used judiciously. There have lately been tendencies to decrease the amounts used.

Draining, Pressing and Settling. For white wine production, the juice is drained to separate it from the broken skins and seeds. The remainder of the juice is separated with a press; the milder the pressure, the lower the extraction of astringent and bitter components. For the highest quality of product, much of the remaining particulate material is removed by allowing the must to settle or by centrifugation. For red wine production, there is no removal of the skins (and no pressing or settling operations) until well after the beginning of fermentation.

To provide some stylistic imprints to their winemaking, some winemakers allow the crushed grapes, usually red ones, to be stored for several days at cool temperatures, without addition of yeast and usually without addition of sulfur dioxide. This procedure is not without difficulties. If the acidity is too low (pH > 3.5), the process can lead to infections by lactobacilli, bringing about ruinous concentrations of acetic acid.

Wine yeasts can be defined as those yeasts which carry out complete fermentation of grape juice (i.e., those having high tolerance to acid and to ethanol) and give an end product with an obvious vinous character with no off-flavors or odors [3]; they are limited to strains of *Saccharomyces cerevisiae* [69] or *S. bayanus* [70]. It was previously thought that wine yeasts were found indigenously in high concentrations in the vineyard, and had something special to do with the style of wine coming from adjacent wineries, in so-called “natural” fermentations, where yeast starter cultures are not used. It is now rather accepted that the indigenous aspect in natural fermentations is the winery itself and the winery equipment [3], [71].

Wild yeasts can be defined as yeasts which are not so tolerant to ethanol and carry out fermentation of grape juice to a few percent of ethanol. These yeast are easily isolated from the surfaces of fresh grapes, and are members of several genera: *Kloeckera*, *Hansenula*, *Hanseniaspora*, *Pichia*, *Candida*, *Metchnikowia*, *Debaryomyces*, *Kluyveromyces*, as examples. In laboratory experiments, these yeasts often produce fermentation products with captivating and intriguing odors which, however, are always very short-lived and disappear when the fermentation is allowed to go to completion by addition of wine yeast.

Grape Juice as a Wine-Yeast Medium. Wine yeasts grow on minimal media; they are capable of making all the cellular components necessary for growth, with the exception of the vitamin biotin. However, wine fermentations require not only

growth of the yeast, but production of cells having sufficient vigor to complete the vinification and to produce the high concentration of the inhibitory product, ethanol. Grape juices generally are abundantly supplied with nutritional components for the yeast biomass and for the fermentation. Furthermore, the high acidities of grape juice, the anaerobic vinification conditions and the resulting high concentrations of ethanol prevent the growth and activity of unwelcome microorganisms.

Yeast Inoculation. In the new-world wine regions, and more and more in the old world, addition of commercially produced wine yeast, in an “active dry” form, as starter culture is standard. The yeasts are manufactured under highly aerobic conditions, which provide them with high concentrations of sterols and unsaturated long-chain fatty acids, called “survival factors”. These give the yeast high tolerance to ethanol. They are also growth factors, but this role is not as demonstrable as their effect on increased yeast viability at the end of fermentation [3]. The active dry yeast usually must be rehydrated with warm water under special conditions. Enough yeast is usually added to give a starting concentration of ca. 10^6 cells/mL. Once fermentation has commenced, the fermenting must can itself be used a starter culture, and transferred to the vats and tanks to start other fermentations. This is a time-honored system, but it has it perils in that too many such anaerobic serial transfers may lead to dilution of the survival factors and loss of ethanol tolerance.

More traditional methods involve the use of indigenous wine yeasts, most likely resident in the winery and winery equipment. Often the winemaker makes a *pied de cuve*, where fresh juice is obtained earlier and the yeast therein allowed to grow to obtain concentrations similar to commercial starters. During the first day or so, it is common practice to stir (to rouse) the *pied de cuve*, allowing aeration and formation of survival factors. Even though the high concentrations of glucose in the juice are inhibitory to yeast growth and fermentation (the Crabtree effect [3]), the formation of survival factors is not.

A third method finding some favor in the new-world regions is the so-called “natural” fermentation, where the winemaker, as in the above procedure, relies on indigenous yeast but usually without the benefit either of the historic situation or the preparation of the pre-starter. The advantages are said to be wines with more complex flavor and greater mouthfeel, and wines thought to have a special style from the source winery. The problems, well understood and guarded against, are the same as with multiple serial transfers.

6.2. Yeast Growth and Fermentation

The first phase of alcoholic vinification is yeast growth, essentially under nonrespiratory conditions, producing ethanol and carbon dioxide. After a several-hour lag period, the yeast begins exponential growth, which continues up to 10^8 cells/mL. The yeast rapidly takes up ammonia and most of the available amino acids. Lysine, histidine, and glycine are not well used. Proline is not used at all under these conditions. The order of uptake of the amino acids depends on strain and the overall nitrogenous complement of the juice [3]. Branched-chain amino acids are sometimes used intact, but in cases of nitrogen deficiency, they are stripped of their amino groups and converted to the corresponding higher alcohols (see Section Alcohols).

When the yeast has reached its resting phase, about one-third of the sugar has been fermented, giving ca. 5 – 6 % ethanol. This concentration has little obvious effect on yeast activity, and the yeast continues to produce ethanol and carbon dioxide and remains suspended. But some time thereafter, the inhibitory effects of ethanol become noticeable, fermentation diminishes, and nonfunctional yeast begins to settle out. Ethanol expresses its toxicity by altering the fluidity of the cell membrane, causing increased permeability and leakage of solutes into and out of the cell [3]. The survival factors seem to reverse the fluidity effect, preventing increased permeability. Sluggish or stuck fermentations can arise from shortage of survival factors or from inadequate biomass vigor due to initial nutritional deficiency [3]. Fermentation continues, if slowly, until the fermentable sugar is gone, or until the ethanol reaches a concentration that is finally toxic to the cells' activity. By this time, most of the yeast has settled to the bottom of the vessel.

Most or all of the wine yeast strains are glucophilic, in that they take up, and ferment, glucose faster than fructose [3]. Thus, near the end of the fermentation, when tests for glucose might show none present, there may still be as much as 40 g/L fructose, as fermentable sugar (Section Carbohydrates).

The apparent conversion of sugar to ethanol is variable when the sugar is given in terms of total soluble solids, as with the Brix and Baumé, etc., scales (see above), rather than in terms of actual sugar, itself. Conversion depends on the initial nitrogenous complement of the juice, since this influences the proportion of sugar going to form biomass or to be used for ethanol. One formula gives the concentration of ethanol (in volume percent) as equal to the initial Brix reading multiplied by a factor varying from 0.55 to 0.64 [72].

Temperature. If the initial temperature of the juice is very high, or if there is no mechanism (refrigeration or water curtains) to cool the fermentation, the heat produced (an increase of ca. 1.3 °C for 1 % sugar fermented [1]) may raise the temperature to a point lethal to the yeast (ca. 37 °C in wine), or too high for producing good quality wine. Kinetic models have been devised to predict ensuing temperatures, based on initial temperature and sugar concentrations [73]. These models take into account the loss of ethanol by evaporation and by the sweeping effect of large volumes of carbon dioxide, which is also temperature dependent [3]. Generally, lower fermentation temperatures are desired for white wines (10 – 18 °C), and higher ones for red wines (20 – 30 °C). Generally, the lower the temperature, the greater the formation of esters and acetals, the “fruity” flavor components [3], often more desirable in simple wines without varietal distinction. With red wine fermentations, the temperatures during the early parts of the fermentation are often allowed to rise for short periods of time to 30 °C, the idea being to extract special color pigment components.

6.3. Post-fermentation Operations

The pressing of red wine vinifications is delayed until sometime toward the end of the fermentation. If it has not been done during the fermentation, if may be done now. If the pressing is delayed too long the wine may be too harsh and rough for early consumption, but these tannin components allow the wine to age well [74]. Sometimes the pressing is delayed for several weeks (“delayed maceration”). These wines are said to have softer tannins.

Protection from Acetobacter. At the end of fermentation, the wine is normally transferred (racked) from its sediment (lees) to a full container (cooperage), or to one with inert gas in the head space (ullage). The anaerobic conditions protect the wine from vinegar spoilage (see Section Organic Acids and Carbonic Acid.) by the ubiquitous obligate aerobic *Acetobacter.* Sulfur dioxide treatment is usually also carried out at this time to help protect the wine from this and other spoilages.

Storage. Wine is stored for variable lengths of time, from several months to several years, depending upon the kind of wine. Treatments also vary, including the encouragement, or not, of secondary fermentations. Sometimes, storage is in the presence of spent yeast lees, often for several months, with stirring of the lees from time to time. Sometimes the wines are stored in inert containers, but often in wooden, usually oak, casks and barrels. This cooperage allows some removal of harsh materials from the wine, but more importantly the extraction of flavor components from the wood, which are complementary to the wine. There is much information and some mysticism regarding the kind of wood, its origin and treatment, the kind of production of the barrel, including the amount of firing (toasting), and the length of times the wines should be stored therein [3].

Stabilization: Racking, Fining and Filtration. Wines often clarify naturally by the settling action during storage, especially when they are also racked from time to time. This process can be accelerated by use of filtration. As with any treatment, filtration has the potential to do some damage to the wine, but there is no damage if filtration is done correctly. Sometimes insoluble materials with adsorptive properties, such as bentonite, egg white, or isinglass, are added. As they precipitate, they remove the unwanted material and settle with it to the bottom, after which the wine can be racked and filtered.

The above treatments are used to render the wine stable with respect to proteins, metal ions (Section Metal Depletion in the Fermentation and Preparation of Wine), tartrates, and microbes. During storage of the wine, any of these problems are usually easily solved with the above-mentioned techniques. However, the problem of continued stability after the wines are bottled and are in the consumers' hands is another matter: the protein becomes a haze, the metal ions catalyze oxidation reactions and the wine becomes brown, the potassium bitartrate crystallizes out, and the microbes cause turbidity and probably off-flavors and odors. Thus winemakers require a battery of stability tests, to assure that none of their wines will come in harm's way.

7. Secondary Fermentations

Ralph E. Kunkee

7.1. Malolactic Fermentation

Malolactic fermentation is caused by special, wine-tolerant lactic acid bacteria which can decarboxylate L-malic acid to L-lactic acid and carbon dioxide [3], [75]. This usually occurs after the end of alcoholic fermentation. The required decarboxylating enzyme is found uniquely in certain strains of *Leuconostoc*, *Pediococcus*, *Lactobacillus*, and *Lactococcus*, the first three having been found in wine. Strains of *Leuconostoc oenos* are by far the most important for commercial wine production.

The main consequences of malolactic fermentation/conversion are:

1. Deacidification of the wine due to loss of one of the carboxyl groups, which is liberated as carbon dioxide gas
2. Utilization and depletion of micronutrients by the growth of these bacteria, rendering the wine biologically stable and generally unable to support further growth of these microorganisms
3. Subtle, but real changes in flavor, in addition to those coming from the change in acidity

The first consequence is of prime importance where grape juices and wines are initially too acidic (e.g., in northern France). The second consequence is of concern at time of bottling of wine, which might be susceptible to malolactic bacteria. Either it should have been stabilized by having had this fermentation or it should now be rendered stable, e.g., by sterile filtration. The third consequence seems to be strain dependent and is desirable, unless the strain produces spoilage flavors or odors. The most commonly identified flavor end product is diacetyl, which, depending on the concentration, has odors associated with sweet and/or spoiled butter. If the amounts made are above the recognition threshold, the wine is properly considered spoiled; but if below, and still detectable, its presence may increase the complexity of the wine and thus be considered a positive attribute [3], [75]. Diacetyl is more noticeable in white wines, where its presence is also more controversial. One of the main substrates for diacetyl formation, at least for leuconostocs, is citric acid but complete management of the formation of this end product is not presently possible.

In the past, winemakers have controlled malolactic fermentation by using the bacteria resident in used cooperage as inocula. Historically, noticeable changes in the wine occurred in the springtime. In modern times, at least in the new world regions, noticeable bacterial activity comes much sooner, usually being complete within a month or two after primary fermentation. The process has been accelerated by suitable adjustments of pH, sulfur dioxide, and temperature. Furthermore, originating in Burgundy, but widely mimicked, wines are retained on their lees (*sur lies*) to provide the bacteria with additional micronutrients extracted from the yeast. However, the ultimate quickening factor has been the California technique of inoculation with starter culture. This has led to the commercial availability of several strains of lyophilized bacteria for this purpose.

Malic acid is not an energy source for these bacteria, and other sources have to be supplied. Nevertheless, the presence of malic acid does stimulate the initial growth rate [3], [75].

7.2. Sparkling Wine

Sparkling wine, of which Champagne is the prime example, is produced by a secondary fermentation of a sweetened base wine to which yeast has been added. The mixture is placed in a heavy walled bottle that withstands the several atmospheres of pressure produced during fermentation. Special tricks, including freezing the necks of bottles after they have been shaken and stored upside down for several months, are used to remove the yeast formed during secondary fermentation [25]. A bulk method (Charmat) is also used, where the yeast is removed by filtration. A new procedure, involving embedding of yeast in alginate gels for the secondary fermentation, shows great promise [22], [76].

7.3. Flor Sherry

The flor sherry process, wherein special yeast form a film on top of “shermat” wine (sherry material), and metabolize it, and similar processes, are described in Section Dessert/Appetizer Wines. The metabolism is actually an oxidation rather than a fermentation. This process can also be adapted to a bulk “fermentation”, in which the yeast are submerged (“submerged flor” process) in the shermat. The wine is put into a pressure tank and subjected to ca. 1 bar with occasional stirring, which serves to increase the oxygen tension in the wine enough to allow the yeast to respire. While this process certainly gives many of the same end products as those produced in Jerez, the later small-scale natural production in wooden cooperage is considered superior.

7.4. Microbial Spoilage

Not all secondary fermentations are desirable. Attention must be paid to the undesirable ones, the spoilages. However, modern commercial wine cellars are relatively free from microbial spoilages, because of regard to established cellar sanitation methodology, along with judicious use of sulfur dioxide and with employment of rough filtration from time to time.

Wine Yeast and Wine Bacteria. Spoilage can originate from otherwise desirable wine yeasts and wine bacteria if they are in the wrong place or at the wrong time. For example, turbidity coming from refermentation of a semidry bottled wine, in the bottle, by a strain of wine yeast, certainly must be classified as spoilage. The same could be true of an esteemed strain of malolactic bacteria being in the wrong place at the wrong time.

Spoilage Yeast. Many wild yeasts (Section Pre-fermentation Operations) will survive in wine and provide some cosmetic problems in bulk cellar storage of wine, problems easily corrected as mentioned above. However, a few genera are damaging, causing turbidity or off-flavors and odors. The most important of these are *Zygosaccharomyces*, *Saccharomycodes*, and *Brettanomyces*. *Zygosaccharomyces* are resistant to sorbic acid, *Saccharomycodes* are resistant to sulfur dioxide, and *Brettanomyces* seem to thrive on wines with minuscule amounts of residual sugar or in presence of new wood [3]. Thus, the definitive control of each of these is filtration. *Brettanomyces* has received most attention, probably because of it ubiquity, the difficulty of completely eliminating it, and the intense controversies over desirability of the putrefactive flavors and odors of its end products [3], [77]. *Dekkera* are the ascosporogenous forms of *Brettanomyces*; their importance in wine has not yet been established.

Spoilage Bacteria. Already mentioned is the potential problem with malolactic bacteria in the improper place. Another type of spoilage by these bacteria is that coming from strains which produce foul-smelling or foul-tasting materials. The identification of these strains is empirical.

The problems with lactobacillus spoilage during improper cold soaking has been mentioned (Section Pre-fermentation Operations). Another spoilage problem with lactobacilli comes from infections of Port wines and other high alcohol sweet wines. Interesting, some strains of *L. fructivorans* (*trichodes*) and *L. hilgardii* can thrive in and spoil wines with 20 % ethanol. This is an old problem that has resurfaced. In all cases, past and present, it is easily controlled with sulfur dioxide [3] .

The problems with and control of aerobic vinegar bacteria *Acetobacter* have are discussed in Chapter Chemical and Physical Composition of Wine. Other potentially dangerous aerobes are wine-tolerant bacilli. This kind of spoilage is problematic; it seems to be generally cosmetic and very localized [3].

[Top of Page]

8. Typicité and Style

Ralph E. Kunkee

One sometimes hears the saying, “wine makes itself”. It is true that when perfect attention is paid to the viticultural practices alluded to above (Chaps. Grapes and Grape Varieties, Viticulture), the grapes reach the winery with the highest possible distinctiveness of variety and when further perfect attention has been paid to avoidance of all kinds of defects (Chap. Secondary Fermentations), the chances of a superb wine “making itself” may be realized. However, more than that, these perfect conditions in fact set the stage for the ultimate in wine crafting — the development of individual styles, or expressions of the winery's (or winemaker's) *typicité*. These exciting modes include exploitation of unusual yeast and bacterial strains, and perhaps the development and isolation of new ones; innovative maceration and fermentation regimes; and imaginative *sur lies* and other storage treatments. The strength of the appellation, or estate bottling, systems has been long thought to reflect not only the *terroir* of the select vineyards, but also to have something to do with the special and historical style, or *typicité*, of the winery methods. Whether this has been true in the past or not, it is reasonable to expect that imaginative use of the above techniques, and ones not yet thought of, will provide the future consumer with wonderful wines not as yet envisioned.

[Top of Page]

9. Sensory Evaluation

Ralph E. Kunkee

"Traditionally, sensory evaluation of wine is perceived as being that done by a wine expert, who evaluates the 'quality' of wine" [78]. Indeed, that is one type of sensory evaluation, which asks which wine is preferred, or more sophisticatedly, but possibly just as imprecisely, which wine has the higher quality. NOBLE [78] points out that these kinds of hedonic or quality evaluations have their purposes, and if done under well controlled conditions by aware and like-minded judges can give some approximation to the meaning of "quality". This is of course the basis for competitive judging of wines for medals — local and international — and the ratings of wines by "scores" in wine periodicals and by wine consultants.

More definitive tests are those asking if the wines are different, what is the difference, and how big is the difference. If done in a sequential fashion it can provide detailed information about wines [78]. These analyses must be done under controlled conditions and with the use of trained subjects. These kinds of tests can also be used to obtain unspecified differences, thresholds, and time – intensity perceptions.

However, the most important new technology for precise sensory evaluation is descriptive analysis. For this a panel initially attempts to identify the most important sensory attributes and descriptive terms of a wine or group of wines, and trains themselves in doing so. Then under blind tasting conditions, wines are rated in terms of these attributes by this panel. After statistic analyses of the panelists' judgements have been made, profiles of the wine odors or flavors are developed which permit an evaluation of the differences among the wines [78].

[Top of Page]

10. Economic Aspects

Ralph E. Kunkee

In 1994, world wine production was 25.6 $\times 10^9$ L, with ca. 74 % (19×10^9 L), coming from Europe, of which only 4 % (10^9 L) was from Germany [79]. However, the consumption of wine in 1994 was: world 22.2×10^9 L, Europe 16.5×10^9 L, Germany 1.8×10^9 L. Thus for the world, and for Europe as a whole, consumption was substantially less than production. And this is not a new situation: European consumption in the early 1970 s was as much as 18.8×10^9 L, and has been decreasing ever since [22]. The only countries to show a substantial increase in consumption over the last several years are Germany, but that is from a very low base when some wine-contamination scandals cut consumption drastically, and the United Kingdom, but even that increase has leveled off in the 1990s [79]. Part of the drop in consumption is due to the displacement of wine by other beverages, especially soft drinks, but also coffee, fruit juices, and milk products [79]. Some of the problems in attempts to analyze or to offer solutions to the downward consumption have to do with the international complexity of the situation. For example, SPAHNI [80] discussed the multidimensional product, the multiregulated industry, the multinationals and the multilateral trade. Whatever the explanation, the consequences are serious. Vineyards are not quickly transformed from grape production to other crops, and thus the decreased consumption has led slowly to substantial inventories. Some reasonable suggestions involve changing strategies in marketing, in public relations, and reaching out to new markets [23]. However, the most consequential effect on consumption has come from an unexpected source, an American television news magazine, *60 Minutes*, on the subject of the "French Paradox", and the publication of the book of the same title [81]. The announcements of the benefits of ethanol in general, or wine in particular, and especially red wine, on human health (Chap. Wine and Health) had a dramatic effect on wine sales and consumption in the United States, at least in the short term.

[Top of Page]

11. Wine and Health (For toxicology of ethanol, see → Ethanol – Toxicology)

Ralph E. Kunkee

Moderate use of wine has long been touted as a health-care giver, long before St. Paul's dictum to Timothy [82]: "Drink no longer water, but use a little wine for thy stomach's sake" and up to its current use as a mild diuretic, tranquilizer, appetite stimulant, soporific and source of non-glucose calories [1]. Wine as a provider of trace elements has also long been realized (Section Essential Trace Elements in Wine). However, it has only been in the last several years the there has been substantial evidence for what many practitioners have long thought was true: that regular, but moderate, consumption of ethanol tends to reduce the incidence of coronary heart disease, apparently by raising the level of high-density lipoproteins in the blood and lowering the low-density lipoproteins (LDL) [83]. Studies have shown some of the mechanisms for these actions, at least from the moderate consumption of red wine [84]. Wine flavonoids from red wines are antioxidants and inhibit human LDL oxidation; resveratrol, another pigment from red wine, also inhibits human LDL oxidation.

1. Morphology and Properties

1.1. Introduction

Not only is wood the most important renewable natural resource in terms of quantity, but because of its composition and versatile properties, its use as a raw material for pulp, structural timber, sawn wood, panels, furniture and other purposes is also economically important. In industrialized countries, wood plays only a minor role as an energy carrier [19]. The total phytomass of the earth is estimated to be 1.24×10^{12} t, of which 80 % is attributed to wood [20]. The potentially utilizable annual wood growth is 1.1×10^{10} t [21].

Data from the Food and Agriculture Organization (FAO) of the UN on forested areas and roundwood removals worldwide are given in Table 1.

The forested area of Germany, for example, covers 10.8×10^6 ha. This is 30.4 % of the total area of Germany, of which 55.1 % is agricultural. Of the forested area, 32.8 % is occupied by spruce, 27.5 % by pine, 14 % by beech, and 8.5 % by oak [23]. According to these statistics, Germany is among the more highly forested countries of the world, but with regard to the forested area per capita, it is one of the less forested, with 0.14 ha per inhabitant.

Finland, in comparison, with 33.8×10^6 ha total land area and 20×10^6 ha forests, has about the same size but nearly twice as much forests as Germany. It has 4 ha forested area per inhabitant, consisting mainly of spruce and pine (40 % each) and birch (16 %). Similarly Sweden, with a total land area of 45×10^6 ha, of which 58 % is forested, has 3.1 ha forests per inhabitant. In the southern part of Sweden spruce is predominant (51 %), followed by pine (29 %). This ratio is reversed in Northern Sweden with 48 % pine and 39 % spruce.

A quite different distribution of wood species is found in southern and tropical countries, where deciduous woods (hardwoods) often outweigh coniferous woods (softwoods).

Germany is a typical wood-importing country. In 1992, 80.3×10^6 m^3 of wood was imported and 27.7×10^6 m^3 of indigenous wood was cut. These figures take into account the different units used to quantify wood products, e.g., tonnes of pulp are expressed as raw wood equivalents in cubic meters (Table 2).

Finland, in contrast, as a typical wood exporting country, in 1992 had 55×10^6 m^3 roundwood removal from indigenous forests (cut wood) and additional 6×10^6 m^3 from Russia. Out of these 20×10^6 m^3 went into the domestic timber industry and 28×10^6 m^3 (plus 6×10^6 m^3 industrial wood residues) into the pulping industry. Finland exports some 1.5×10^6 t pulp and 6×10^6 t paper and cardboard, mainly to Western Europe, covering ca. 32 % of its national exports by wood products.

Important importing and exporting countries of wood, semifinished wood products, pulp, and paper are listed in Table 3.

Table 1. Forests and roundwood removals worldwide according to [22]

Area	Forested area (1990)			Roundwood removals (1991), 10^6 m^3				
	10^6 ha	% of land area	ha/inhabitant	Total	Coniferous wood	Deciduous wood	Wood for processing	Wood for combustion

∗ GDP = Gross domestic product.

The versatile technological properties of wood result from its anatomy and the chemical properties of its three main components, cellulose, lignin, and hemicelluloses, which, in turn, are affected in different ways by wood extractives occurring as minor components.

1.2. Biology of Wood

All woody plants reproduce by seeds and are part of the Spermatophyta. This systematic division is split into the Gymnospermae, to which the softwoods belong, and the Angiospermae, to which the hardwoods belong. The Monocotyledoneae are part of the Angiospermae; some of them (e.g., bamboo and rattan) develop woody

tissue but are for various reasons maintained as a separate entity.

Wood, except for the Monocotyledoneae, is defined as the inner tissue of stems (see Fig. 1), branches, and roots of perennial plants. It acts as a transport system for water and mineral solutes between the root tips and the parts above ground, serves as storage tissue for reserve material, and provides the plant with mechanical stability. Wood is surrounded by the *cambium* (Fig. 2), which consists of a few layers of meristematic cells, and the bark, which functions both as a transport system for assimilates and as protection against environmental influences. The cambial cells undergo frequent division during the vegetation period, producing wood cell initials in the adaxial direction and bark cells in the abaxial direction. With time, the wood cell initials differentiate and form the taxon-specific arrangement of functionally and morphologically different cell types.

Figure 1. Macroscopic appearance of a *Pinus sylvestris* wood segment with wood and bark

1.2.1. Anatomy [26]

The histological term for wood as the tissue inside the cambium is *xylem*. Its formation is restricted to the annual vegetation period and therefore represents a periodic process. In the northern temperate zone, typical growth rings are laid down with subdivision into *earlywood* and *latewood* that determine the beginning and end of the growing season. A growth ring is strictly correlated with one year, whereas in the tropics and subtropics the growth increments may reflect alternating wet and dry seasons, not necessarily an annual cycle.

Figure 2. *Populus robusta*: Cross-section through the cambial area, adaxial xylem, and abaxial phloem
Light micrograph (LM)

Figure 3. *Calamus caesius*: Cross-section through a rattan stem (LM)

Monocotyledoneae do not possess a cambium and therefore lack the secondary thickening characteristic of gymnosperms and most

angiosperms. Their woody tissue consists of numerous axially oriented vascular bundles, which are embedded in a parenchymatous ground tissue (Fig. 3). Within the vascular bundles, different cell types are associated with the main functions of water and assimilate transport, mechanical support, and to a certain extent, storage of reserve material. In the axial direction, the stem is subdivided into long internodes and short nodes.

The following sections describe wood formed by gymnosperms and angiosperms.

1.2.1.1. Cell Types

Wood in its unique structure is composed of vast numbers of cells. According to their morphology and function, four groups of cell types exist: parenchyma cells, tracheids, fibers, and vessels. *Parenchyma cells* in living wood contain cytoplasm (Fig. 4) and are involved in various processes such as metabolic pathways, short-distance transport, and storage; they form horizontal rays as well as axially oriented strands. Axial parenchyma is much more frequent in hardwoods, where it tends to form distinctive patterns, particularly in tropical timber species. *Tracheids* are the predominant axial cell element in softwoods that provide both water conduction and mechanical support. Tracheids also occur in some hardwoods. They are located adjacent to the vessels (vasicentric tracheids), or they resemble vessels (vascular tracheids) with the sole function of water transport. *Fibers* occur exclusively in hardwoods and represent specialized elements for mechanical support. Slight differences in morphology have given rise to a differentiation between "fiber-tracheids" and "libriform fibers." However, since continuous intergrading exists between them, the general term fiber is commonly used. *Vessels* are specialized elements for long-distance transport of water and mineral solutes in hardwoods; they are composed of individual vessel members that are associated to form a continuous channel with a length of 50 – 60 cm in some genera (*Populus, Fagus*) or greater (*Quercus*). During maturation of the vessels the end walls of the individual members abutting on other members above and below are removed partly or entirely by enzymatic action; this process results in a rather different appearance of the so-called vessel perforation plates.

Figure 4. *Betula pendula*: Ray parenchyma cell with numerous starch grains (S); P = Phenolic body
Electron micrograph (EM)

Tracheids and vessels reach functionality only after the death of their cytoplasm. Fibers have commonly been considered dead cells too, but in some species, a few cells retain their cytoplasm over a long period after completion of wall thickening, in the extreme, up to heartwood formation. These fibers are termed living fibers and may store starch.

1.2.1.2. Softwoods

Softwoods (coniferous woods) exhibit a simpler structure than hardwoods (deciduous woods). They are composed mainly of tracheids as the principal cell type in the axial direction (Fig. 5 A). Tracheids of softwoods are extremely elongated elements with a length of 2.0 – 5.0 mm. Cell size, wall thickness, and lumen diameter vary greatly, with thin walls and wide lumina in earlywood tracheids but extreme wall thickening and narrow lumina in the latewood tracheids. The latter contribute mainly to mechanical stability, whereas the earlywood tracheids are conductive rather than supporting elements. Tracheids may also be horizontally oriented, forming lower and upper margins of the rays in some genera of Pinaceae. In some softwoods, axial parenchyma is absent (e.g., *Picea, Pinus*) or sparse (e.g., *Larix)*; in others it is of regular occurrence (e.g., *Podocarpus, Juniperus*). Axial and radial resin ducts are characteristic features of some genera of Pinaceae (e.g., *Picea, Larix, Pinus, Pseudotsuga*) and are lined

Figure 5. A) *Cedrus libani*: Arrangement of tracheids and parenchymal cells in softwoods (EM); B) *Quercus cerris*: Ring-porous hardwood showing large-diameter earlywood pores and narrow latewood pores (EM); C) *Fagus sylvatica*: Semi-ring-porous hardwood (EM); D) *Acer platanoides*: Diffuse-porous hardwood (EM)

by parenchymatous epithelial cells responsible for the production and posterior secretion of resin into the ducts.

1.2.1.3. Hardwoods

The evolutionary advanced hardwoods possess a functionally and morphologically more diversified structure. The most distinctive feature is the occurrence of vessels, alternatively called "pores" when observed on transverse surfaces. Vessels vary in size and distribution, especially within a discernible growth increment. This diversity is called porosity and represents a very important feature for the identification of hardwoods attributed to three groups: *ring-porous*, *semi-ring-porou,*, and *diffuse-porous*. *Ring-porous woods* (Fig. 5 B) show distinct differences in the size of vessels within one growth increment; earlywood vessels are larger in diameter than latewood vessels, with an abrupt transition between both. Hence, in some cases the earlywood portion becomes clearly visible as a pore-ring even with the unaided eye. *Semi-ring-porous woods* (Fig. 5 C) are characterized by a gradual change from large-diameter earlywood vessels to small latewood vessels. *Diffuse-porous woods* (Fig. 5 D) display vessels of nearly the same diameter throughout one growth increment. The variation within a species, however, may range sometimes from ring porous to semi-ring porous or from semi-ring porous to diffuse porous. Vessels may be arranged in tangential bands, may exhibit a diag-

onal or radial pattern, or may reveal a branched appearance to form a dendritic pattern. Vessels may also occur solitarily, as groups in radial multiples of four or more, or as irregular clusters.

Axial parenchyma cells are much more abundant in hardwoods than in softwoods (Table 4). The amount and various distributional patterns display a marked diversity. The position of axial parenchyma cells in relation to vessels is used for a general subdivision into two types of parenchyma. The term *apotracheal parenchyma* reflects the isolation of vessels against axial parenchyma by other cells, whereas *paratracheal parenchyma* describes the association of axial parenchyma strands with vessels. Rays in hardwoods may be large or small in width and height, or both types may occur within one species.

Table 4. Percentage of cell-type volume in some wood species

Species	Vessels	Fibers	Ray parenchyma	Axial parenchyma
Douglas fir (*Pseudotsuga menziesii*)		93	7	
European spruce (*Picea abies*)		95	5	
Pine (*Pinus sylvestris*)		93	6	
Aspen (*Populus tremula*)	26	61	13	
Birch (*Betula alba*)	25	65	8	2
Oak (*Quercus robur*)	8 – 40	44 – 58	16 – 29	sparse – 5
Ash (*Fraxinus excelsior*)	12	62	15	11
Beech (*Fagus sylvatica*)	39	40	16	5
Framiré (*Terminalia ivorensis*)	20	53	17	10
Kosipo (*Entandrophragma candollei*)	12	45	25	18
Mahogany (African) (*Khaya ivorensis*)	18	57	21	4
Dark red meranti (*Shorea macrophylla*)	29	41	12	17
Teak (*Tectona grandis*)	12	66	16	6

1.2.2. Secondary Changes

With increasing age and secondary thickening of a woody plant the more centrally located xylem of many species undergoes natural changes. Consequently, the xylem must be subdivided into two parts. In a living tree the xylem portion close to the cambium serves as a pathway mainly for water and mineral solutes, but it also has a storage function; its parenchyma cells are physiologically active and involved in various metabolic processes. The more centrally located wood portion in mature trees, however, does not contain living parenchyma. In general, the terms *sapwood* for the outer, and *heartwood* for the central portions are used. Transition from sapwood to heartwood usually occurs within a narrow zone of a few cell rows, resulting in a slightly undulating sapwood – heartwood boundary. In most cases, the heartwood has a significantly darker color than the surrounding sapwood (Fig. 6), with certain variation of the width of the sapwood between and within species. Besides the obligatory formation of such a distinctly colored heartwood, some tree species develop less colored or nearly colorless heartwood; all of those species are therefore grouped into regular heartwoods.

Figure 6. *Robinia pseudoacacia*: Division of the wood into light sapwood and dark heartwood

Other tree species such as *Betula* or *Fraxinus* are not able to form heartwood under unaffected growth conditions. However, all woody plants develop *discolored wood* as a result of environmental influences (e.g., injury, attack by microorganisms, severe frost). The boundary between unaffected and discolored wood then often moves across a larger number of growth increments with an irregular periphery. Discolorations may also be induced in regular heartwood as a secondary process [27]. The misleading terms "false heartwood," "pathological heartwood," and "frost heartwood" are often used for these environmentally initiated changes. The main criteria for the differentiation between heartwood and discolored wood are as follows: heartwood is characterized by increased natural durability and lower moisture content in comparison to sapwood; in discolored wood, however, the durability does not increase, and the moisture content may rise even above the sapwood level.

Figure 7. *Quercus robur*: Tylosis development – tylosis initials protrude from a parenchyma cell into a vessel (EM)
T = Tylosis; P = Parenchyma cell; VL = Vessel lumen

The change from sapwood to heartwood during natural heartwood formation in hardwoods is frequently accompanied by the occlusion of vessels. The lumina of some species are more or less filled with often dark-staining material secreted from adjacent parenchyma cells. Other species develop *tyloses*, representing balloon-like protrusions from parenchyma cells through the pits into adjacent vessels (Fig. 7).

1.2.3. Cell Wall Formation and Architecture

Walls typically envelop the cytoplasm of all plant cells to impart protection and firmness. Stabilization of a multicellular plant body is sustained by the continuum of adhering walls of all cells. The cell walls consist primarily of an amorphous polysaccharide matrix of pectins and hemicelluloses as well as crystalline cellulose – the basic structural polysaccharide, which is aggregated in the form of microfibrils. Non-polysaccharide components, of which the most important is lignin, are finally incorporated. This combination of different chemical constituents determines the physical properties of cell walls. Details on the chemical composition of cell walls are given in Section 1.3.

Cell wall formation starts with the division of a cambial initial. A daughter cell becomes separated first at the equatorial plane by a thin, tangential wall, which consists mainly of pectic material. This initial layer, common to both adjacent cells, is termed the *middle lamella* (ML) and functions as a cementing substance between cells. At this early developmental stage the young wood cell begins to deposit new wall material against the ML. In contrast to the ML, this new layer contains cellulosic material embedded in a pectin- and hemicullose-containing matrix. This layer represents the first-formed cell wall layer and is called the *primary wall* (P). Here, the cellulose microfibrils show a dispersed texture. Both middle lamella and primary wall are extensible to allow cell expansion during differentiation. Cellulose fibrils and matrix material are continuously incorporated into the growing wall. As the developing wood cell approaches final size, deposition of the stiff secondary wall occurs. Secondary walls in most cases show a subdivision into three layers (S 1, S 2, S 3), with the narrow S 1 as the oldest layer next to the primary wall, the S 2 layer mostly representing the thickest portion, and the sometimes barely

discernible or thin S 3 layer forming the interface with the cytoplasm in living cells or the cell lumen in dead cells. The main constituents of the developing secondary wall are hemicelluloses and, in a distinctly higher proportion than in the primary wall, cellulose. The microfibrils of all secondary wall layers are laid down in parallel arrays: in the S 1, the mean angle with the longitudinal cell axis is 50 – 75°; microfibrils of the S 2 appear more closely packed, with an orientation of 10 – 30° to the cell axis; in the S 3 layer, microfibrils exhibit a mean angle of 60 – 80° with the cell axis (Fig. 8). Sculpturing on the lumen surface of the S 3 layer is sometimes observed (e.g., the "warty layer" in some softwoods and hardwoods). Incrustation with lignin completes wall development.

Figure 8. Schematic representation of wall architecture

The formation of microfibrils during wall thickening takes place at the interface between plasma membrane and cell wall. Fine structural investigations on differentiating plant cells performed in the 1970s and 1980s revealed specific structures within the bilayered plasma membrane: terminal globules in the outer leaflet [28] and rosettes in the inner leaflet [29]. Both terminal globules and rosettes are probably part of the cellulose-synthesizing apparatus. The position of the terminal globules at ending imprints of microfibrils in the membrane implies that they may represent sites of cellulose synthases. The membrane rosettes, in most cases a complex of six subunits, are also believed to be structures with cellulose synthase activity; their frequent occurrence in certain phases and sites of wall synthesis may reflect involvement in microfibril synthesis. Future research must clarify the details of this putative structure – function relationship. Besides the obviously membrane-bound synthesis of cellulose microfibrils, their orientation also appears dependent on membrane-associated structures, the membrane-underlying microtubules. These cortical microtubules may act as guidelines for the synthase complexes within the plasma membrane during microfibril elongation.

At the onset of secondary wall thickening, the deposition of wall material is interdicted along some primary wall areas. These develop into *pits* that represent specific pathways for the conduction of water and mineral solutes. Pits therefore appear as well-defined areas connecting neighboring cells through a thin membrane composed of a middle lamella and a primary wall layer on each side. With rare exceptions, a conduit between two cells consists of a pair of pits. *Bordered pits* show the secondary wall overarching the membrane on both sides, thus reducing the pit aperture. This is true both for pits between the tracheids in softwoods (Fig. 9 A) and for those connecting hardwood tracheids, fibers, and vessels with each other. *Half-bordered pits* generally occur between those cell types and a parenchyma cell with the unbordered part at the parenchyma side (Fig. 9 B). *Simple pits* are without border and connect two adjacent parenchyma cells (Fig. 9 C). Direct cytoplasm contact between parenchyma cells is maintained by *plasmodesmata*, small strands of cytoplasm that extend from cell to cell through perforations in the pit membrane.

1.3. Chemistry of Wood

1.3.1. Chemical Components of Wood

The main components of the wood cell wall (wood substance) are cellulose (→ Cellulose), lignin (→ Lignin), and hemicelluloses. The proportion of cellulose in the most common European woods is 41 – 43 %, whereas the lignin content in coniferous woods (27 – 28 %) is higher than that in deciduous woods (22 – 24 %). Correspondingly, hemicelluloses occur in higher concentrations in deciduous woods (30 – 35 %)

Figure 9. Electron micrographs of different types of pits

than in coniferous woods (25 – 30 %). Compression wood contains more lignin (ca. 40 %), and tension wood (e.g., poplar) more cellulose (> 50 %). Differences are also found in tropical or subtropical types of wood. Within one wood species, age, location, and growth conditions can also play a role.

Most European woods also contain 1 – 3 % extractives and 0.1 – 0.5 % mineral components, which can be determined as ash. Higher contents of extractives have been found in certain types of wood (up to 10 % resins in pines, and tannins in quebracho and eucalyptus); in others, larger quantities of inorganic salts are found. The chemical compositions of some important types of wood are given in Table 5. Due to the lack of analytical methods that allow a clean separation of the wood components, the percentages given in Table 5 suffer from different isolation conditions used by different authors.

The *extractives* consist of a large number of low molecular mass compounds, which can be extracted from wood with organic solvents (terpenes, fats, waxes, and phenols) or hot water (tannins and inorganic salts). Depending on the quantity and the class of compound, which are specific to the tree type and genus to some extent, the extractives affect the chemical, bio-

logical, physical, and optical properties of the wood to varying degrees. As the swelling and biodegradability may be significantly reduced by lipophilic resins they improve the dimensional stability and durability of wood, while other physical and chemical properties, e.g., during mechanical and chemical pulping, sawing, or painting, are negatively affected.

Coniferous woods contain mainly *terpenes*, which can be obtained from pines by resinification of the living tree (→ Resins, Natural, Chap. 5.2.1.) or as turpentine (monoterpenes) (→ Turpentines) and tall oil (diterpenes, resin acids) from kraft (sulfate) pulping (→ Tall Oil). *Long-chain fatty acids* are also present in tall oil and arise from fats and waxes in the wood. In other types of wood (oak, chestnut, eucalyptus, and quebracho), *tannins* and *flavonoids* predominate. *Phenolic compounds* (lignans and stilbenes) are found mainly in coniferous wood (spruce and pine), whereas *sterols* (mainly β-sitosterol) are found in smaller quantities in almost all types of wood. The *mineral components* are mainly carbonates or glucuronates of calcium (40 – 70 %), potassium (10 – 30 %), magnesium (5 – 10 %), iron (up to 10 %), and sodium. Other metals, such as manganese and aluminum, are also present as cations in smaller quantities, which are often dependent on the location. Oxalate, phosphate, and silicate anions can also be found.

Lignin is a cross-linked macromolecule made up of phenylpropane units (C_9), which are linked together by at least ten different C−C and C−O bonds. The irregular structure of lignin arises from its biosynthesis, in which the last step is a nonenzymatic, random recombination of phenoxy radicals of coniferyl, sinapinyl, and *p*-coumaryl alcohols. The dimeric and oligomeric intermediates, obtained in vitro in the dehydrogenative polymerization of coniferyl alcohol, formed the basis of the constitutional scheme of spruce lignin proposed by Freudenberg (→ Lignin, Chap. 3.) [31]. Freudenberg's hypothesis of lignin biosynthesis was later confirmed for beech lignin by degradation with thioacetic acid and ^{13}C-NMR spectroscopy [32]. Variations in the chemical reactivity of lignin arise from the proportions of the three structural units. Whereas coniferous lignin consists mainly of guaiacylpropane (4-hydroxy-3-methoxyphenylpropane) units (G), deciduous wood lignins also contain up to 50 % syringyl (3,5-dimethoxy-4-hydroxyphenyl) groups (S), and compressive wood lignins up to 40 % *p*-hydroxyphenylpropane (H) units. Up to 30 % of the latter also occur in grass lignins.

On an industrial scale, lignin and hemicelluloses are removed from wood by pulping (→ Paper and Pulp, Chap. 1.3.) under partial degradation and isomerization. Lignin can be removed from wood more selectively under laboratory conditions by using chlorine, chlorine dioxide, or peracetic acid. From the residue known as holocellulose, hemicelluloses can be extracted either with 17.5 % sodium hydroxide – with α-cellulose as extraction residue – or with dimethyl sulfoxide.

Hemicelluloses are polysaccharides and differ from cellulose in that they consist of several sugar moieties, are mostly branched, and have lower molecular masses with a degree of polymerization (DP) of 50 – 200. The two main types of hemicelluloses are xylans and glucomannans. Structural and quantitative differences exist between hemicelluloses in deciduous and coniferous woods. *Deciduous woods* contain 10 – 35 % *O*-acetyl-4-*O*-methylglucuronoxylan and 3 – 5 % glucomannan, whereas *coniferous woods* contain 10 – 15 % arabino-4-*O*-methylglucuronoxylan and 15 – 20 % *O*-acetylgalactoglucomannan [33]. The upper part of Figure 10 shows a section of the structure of a coniferous wood galactoglucomannan. The molecule chain ("backbone") consists of β-(1,4)-glycosidically bonded glucose and mannose units in the ratio 1:3, with 0.1 – 1 α-(1,6)-bonded galactose moiety and 0.24 acetyl group per glucose unit as side groups. In the lower part of Figure 10, a deciduous wood xylan is depicted with β-(1,4)-glycosidically bonded xylose units in the chain, 0.1 α-(1,2)-4-*O*-methylglucuronic acid moiety, and 0.7 *O*-acetyl group per xylose unit as side groups.

Deciduous wood glucomannans contain only ca. 1.5 mannose units and no side groups per glucose unit; coniferous wood xylans have 0.2 α-(1,2)-4-*O*-methylglucuronic acid and 0.13α-(1,3)-L-arabinofuranose groups per xylose unit. Larch wood contains 10 – 25 % arabinogalactan, which consists of β-(1,3)-bonded galactose moieties in the main chain, with β-(1,6)-bonded short side chains of D-galactose and L-arabinose units. This compound is usually classified as a pectin. Pectins (→ Polysaccharides, Chap. 3.1.) occur in small quantities in the primary walls of all wood cells.

The biogenesis of D-glucuronic acid, D-galacturonic acid, D-mannose, D-galactose, D-xylose, and L-arabinose starts from guanosine diphosphate(GDP) – glucose and involves epimerization, dehydrogenation, and decarboxylation.

Cellulose. In terms of quantity, cellulose is the most important wood component. It consists of unbranched long chains of β-(1,4)-glycosidically bonded D-glucose units, which exist as pyranose rings in the $^4C_1$ conformation with equatorial OH and CH_2OH groups. The DP of native cellulose is between 10 000 and 14 000. In industrial pulping however, cellulose is degraded to DP values of 1000 – 3000. Annually ca. 130×10^6 t of pulp is used for paper production worldwide, and only ca. 5×10^6 t for the production of viscose and cellulose esters (acetate, nitrate, and mixed esters) and ethers (methyl-, carboxymethyl-, and hydroxyethylcellulose). The byproducts lignin and hemicelluloses present in the waste liquor are incinerated to recover the pulping chemicals. They pollute the wastewater from pulping factories to a great degree.

1.3.2. Distribution of Components in the Cell Wall

The distribution of cellulose, lignin, and hemicelluloses varies among the individual layers of the wood cell walls. Lignin is formed at a distance of ca. 10 cell layers from the cambium only after formation of the cells themselves. It is deposited in the spaces between the cellulose fibrils in the secondary wall and between the cells in the middle lamella, so that its concentration in the middle lamella and in the corner sections is highest (70 – 90 %), while only 20 % is found in the secondary wall. Because of the larger volume of the secondary wall, the main quantity of lignin (63 – 74 %) is found in this layer, which also contains ca. 90 % of the cellulose and 70 – 80 % of the hemicelluloses, with the concentration decreasing toward the lumen. The lignin distribution in the wood cell wall can be determined from the absorption of UV light (240 nm) by very thin (0.1 µm) microtome sections under the microscope [34] (Fig. 11).

Figure 10. Sections of coniferous wood galactoglucomannan molecules (above) and deciduous wood 4-*O*-methylglucuronoxylan molecules (below)

Figure 11. A) UV micrograph of microtome cross-section of an earlywood tracheid of black spruce (*Picea mariana*); B) Densitometric lignin distribution curve along the dotted line [34].

The proportions of lignin and tissue in the secondary wall, and the narrow and corner sections of the middle lamella in early and late spruce tracheids, are shown in Table 6. More lignin is found in the narrow and corner sections of the middle lamella in earlywood (28 %) than in latewood (19 %).

1.3.3. Macromolecular Structure of Cell Wall Components

Of the three cell wall components, only cellulose has a partially (ca. 70 %) ordered crystalline structure, whereas the hemicelluloses and lignin are amorphous. Because of regular hydrogen bonds, the cellulose chains are ordered to form elemental fibrils with a diameter of ca. 3.5 nm and alternating crystalline (micelles) and amorphous regions. These, in turn, are associated to form microfibrils, which are ca. 10 times thicker. The microfibrils form layers (Fig. 8) between which the lignin and the hemicelluloses are deposited. Chemical bonds are formed between the α-C atoms of lignin and the hydroxyl groups of the hemicelluloses (benzyl ethers), which prevent the leaching of lignin from the wood by neutral organic solvents. Irregular hydrogen bonds also exist between the hydroxyl groups of lignin, the hemicelluloses, and cellulose, through which a close, but irregular network of the three components is formed.

The cellulose microfibrils are first formed biogenetically as the framework of the cell wall, whose growth is finished before lignification begins. Lignification occurs in the secondary wall by filling the spaces between the cellulose mi-

Table 6. Distribution of lignin in black spruce tracheids (*Picea mariana*) [35]

Wood	Morphological differentiation	Relative absorbance	Tissue volume fraction, %	Lignin	
				% of tissue	% of total
Earlywood	secondary wall	1.0	87	22	72
	narrow sections of middle lamella	2.2 *	9	50	16
	corner sections of middle lamella	3.8	4	85	12
Latewood	secondary wall	1.0	94	22	81
	narrow sections of middle lamella	2.7 *	4	60	10
	corner sections of middle lamella	4.5	2	100	9

* Measured for the compound middle lamella. Measurements on oblique sections suggest absorbance values of 3.8 and 2.0 for the true middle lamella and primary wall sections, respectively.

crofibrils, whereby monomeric phenoxy radicals add to already formed polymers (endwise polymerization).

1.4. Physical Properties

Wood is hygroscopic; i.e., it exchanges water vapor with its environment. In a uniform climate, the moisture in wood is in equilibrium with this climate. The *moisture content of wood* is defined as the mass of moisture contained in the wood relative to the mass of the absolutely dry wood substance and is given as a percentage. Figure 12 A shows the relation of the equilibrium moisture content to the relative humidity of the air at 20 °C. This sorption isotherm is approximately valid for most wood species. Only species that contain hydrophobic components (e.g., teak, afzelia, and movingui) have significantly lower sorption isotherms.

The following moisture levels are recommended for the use of wood:

Furniture, interior decoration	6 – 10 %
Parquet	7 – 11 %
Windows, outer doors	10 – 15 %
Covered, open buildings	12 – 18 %

Adherence to these standard moisture levels during the final working and incorporation of wood reduces later variations in moisture levels and dimensions to a minimum.

In the hygroscopic region (i.e., below fiber saturation; FS in Fig. 12), the dimensions of wood increase (swelling) with increasing moisture content and decrease (shrinkage) with a corresponding decrease in moisture content. Figure 12 B shows the variation with moisture levels in the *degree of swelling* of spruce in the three main directions. Wood can also store liquid water in the pore spaces above the FS level, but no further swelling takes place. Because of the usual surrounding climates, the range of wood moisture content is particularly important between 5 and 20 %. In this range, wood swells and shrinks by ca. 0.2 % in the radial and 0.3 % in the tangential direction on 1 % change in moisture content.

The density of the pure cell wall substance is close to 1.5 g/cm^3 for all wood species. However, the *density* of a piece of timber (mass of wood relative to volume including pore spaces) covers a wide range from ca. 0.17 (balsa) to 1.2 g/cm^3 (pock wood). This range results from the different proportion by volume occupied by the cell wall in a particular species – in balsa ca. 11 %, in pock wood ca. 80 %. The remaining volume is pore space, which is filled with air in dry wood and water in wet wood. Density values quoted refer mostly to standard climate conditions (20 °C and 65 % relative humidity), i.e., a wood moisture level of ca. 12 %, as do the other moisture-dependent properties of wood. Since the density is a measure of the proportion of cell wall in the total wood volume, the following parameters tend to increase with increasing density: the modulus of elasticity and strength, abrasion resistance and hardness, and thermal conductivity.

Because of the structure of wood, all the properties mentioned, such as swelling and shrinkage, are anisotropic (i.e., direction dependent). The advantage of wood as a building material lies in the combination of high *strength* in the fiber direction and low thermal conductivity perpendicular to it. Wood is therefore particularly suitable for load-bearing and heat-insulating roof and wall components. Table 7 lists the average densities, moduli of elasticity, and strengths of a selection of wood species. It shows that

Figure 12. A) Sorption isotherm at 20 °C; B) Relation between degree of swelling and equilibrium moisture content in the three main directions of spruce
a) Longitudinal; b) Radial; c) Tangential

for wood species in general, the compressive strength in the fiber direction is approximately half the value of the tensile strength. However, as the direction of the load deviates from that of the fibers, the tensile strength decreases more sharply than the compressive strength. Wood should therefore not be subjected to tension perpendicular to the fiber direction (cleavage cracks due to shrinkage). However, application of compression perpendicular to the fiber direction is possible and frequently leads only to densification, not breakage.

In each case, the elastic properties and strength in the hygroscopic region decrease with increasing moisture content. However, above fiber saturation (use of wood in marine construction work), these properties are no longer altered by the moisture level in the wood.

For wooden floors, *abrasion resistance* and hardness play an important role. The relation between *Brinell hardness* H_B and density ϱ_N is given by the equation

$$H_B = 76^{\bullet}\varrho_N - 24.5 \left(\mathrm{N/mm^2}\right)$$

for the important density range of 0.5–1.0 g/cm^3.

The following are values for the *thermal conductivity* perpendicular to the fiber direction:

Spruce, pine, and fir	$0.13\,\mathrm{W\,m^{-1}\,K^{-1}}$
Beech and oak	$0.20\,\mathrm{W\,m^{-1}\,K^{-1}}$
Azobe and greenheart	$0.28\,\mathrm{W\,m^{-1}\,K^{-1}}$

2. Wood-Based Materials

2.1. Introduction

Wood has a number of favorable properties and has been a valuable material from time immemorial. It is relatively easy to obtain and can be worked readily. Wood has high strength at relatively low weight and has a decorative effect because of its color and graining. When used properly it often remains functional for hundreds of years even under adverse climatic conditions (e.g., outdoors).

Unfortunately, wood also possesses some less favorable properties. Since the arrangement of the elongated cells that form the bulk of the wood is predominantly parallel to the trunk (see Fig. 5), wood properties are anisotropic. Thus, the strength in the direction of the trunk is much greater than that perpendicular to it. Wood is also a hygroscopic material. Its moisture content is determined by the surrounding climate (see Section 1.4). Variations in the moisture level of wood in the hygroscopic region give rise to

Table 7. Average values for certain properties of a selection of wood species determined for small, defect-free test pieces at 12 % moisture content ∗

Wood species	Density, g/cm^3	Modulus of elasticity, N/mm^2	Strength, N/mm^2		
			Tension	Bending	Compression
Softwoods

∗ The flexural strength is valid for loads perpendicular to the fiber direction, the tensile and compressive strengths for loads in the fiber direction of the wood.

variations in its dimensions. These variations, in turn, differ depending on whether the anatomical direction is longitudinal, tangential, or radial. This phenomenon is known as warping. Wood is a typical natural material and is therefore inhomogeneous. It has growth irregularities and faults, such as knots, as a result of which the yield of usable material is often low. The lengths and particularly the widths available are limited, thus making the use of wood for certain applications difficult or impossible.

The primary aim of the development of wood-based construction materials is to eliminate or reduce the undesirable properties as much as possible. At the same time, attempts are made to retain the favorable characteristics and make them predominate.

Conversion of solid wood into wood-based materials always follows the same principle. Cordwood is cut into small pieces that are combined with a suitable binder (Fig. 13). Cutting into smaller pieces involves sawing, peeling, chopping, or defibration. Boards, veneers, particles of varying dimensions, and fibers are thus produced. As the size of the piece decreases, the properties of the wood-based panel or construction material differ more and more from those of wood. The wood-based material becomes more homogeneous, and the possibilities for size enlargement in two or three dimensions and molding increase. However, at a comparable density, the strength decreases and the typical wood character is lost. This is exemplified by the changing properties in the series sawn timber, plywood, particle board, and medium-density fiberboard (MDF).

2.2. Laminate Bonding

2.2.1. Laminated Structural Timber (Glulam)

2.2.1.1. Development

The art of building with wood is many centuries old. Unfortunately, the quantity of trunk wood of sufficient dimensions available for making load-bearing building components with the spans desired is continuously decreasing. This consideration gave the German carpenter Otto Hetzer the idea in 1906 of using a completely new method. He cut the cordwood into boards and glued the graded and dried lamellar boards together with adhesive to form new cross-sections (glulam girders, i.e., glued laminated girders, or laminated beams).

Figure 13. Classification of wood elements (according to MARA 1972 [18])

The actual breakthrough of the process for using glulam girders in building occurred in 1930 with the development of synthetic adhesive resins. Large-scale industrial production opened up new areas of application for this method. Besides being used in tall buildings, glulam girders were used in airplanes (Mosquitoes in England and the Spruce Goose in the United States), sometimes with large wing spreads, and for mine casings because of their antimagnetic properties. Glulam girders are now used mainly for building in central and northern European countries and North America, where wood has traditionally been used widely for this purpose.

Glulam girders were traditionally produced in small, handcrafting workshops. These have been replaced in recent decades by efficient industrial plants, which use machine systems and automatic production lines and can offer quality assurance.

2.2.1.2. Construction and Production

Raw Materials. Laminated wood is made mostly from spruce, which is the easiest wood to process and fulfills the usual requirements concerning strength and durability.

Pine, larch, and Douglas fir are also used in special cases. Hardwoods are generally used only for building components that must support very heavy loads. For some hardwoods, the effect of wood components on the durability of adhesive compounds is not entirely clear.

Adhesives. In a normal indoor climate and for building components protected from weathering, glues based on urea resins are used. For building components that are exposed to strong climatic variations or weathering, weather-resistant adhesives based on phenol – resorcinol – formaldehyde (PRF) are employed. These PRF resins give a dark brown glue line, unlike adhesives based on amino resins. In the 1990s a special glue type for bonding laminated was developed based on using melamine – resorcinol – formaldehyde resins. These bondings are highly resistant to boiling water and give a pale glue line.

Production. Lamellar boards are sawed from cordwood trunks. The boards are predried to ca. 10 % residual moisture, graded, and then bonded in automatic plants to form continuous boards with dovetail joints. The moisture in the boards to be glued should be 2 – 3 % below the expected equilibrium moisture level. Variations in the moisture content of the different boards

should not be greater than 2 %. The broad sides of these joined boards are planed until smooth and uniformly coated with adhesive. In constructing the cross-sections, particular attention is paid to the positions of the annual rings in the boards (Fig. 14). The rifts (vertical) and the flats (horizontal) should be distributed regularly.

Figure 14. Lamellar construction of a glulam girder cross-section

Depending on how exactly the surfaces fit together, 400 – 600 g of adhesive liquor is applied per square meter. Glued boards are stacked and stored under pressure at room temperature or slightly higher (40 °C) so that the adhesive resin cures after a few hours and a composite beam is formed.

The geometry of the beams and their cross-sections can be varied widely and adapted to requirements of static calculations and aesthetics. Lamination allows bent beams with differing profile shapes and spans of 60 – 100 m to be produced.

Besides individually produced building components, the continuous production of laminated wood as a band was recommended [36]. Such standardization with regard to dimensions is expected to improve the economics of this process.

2.2.1.3. Properties

Laminated wood is clearly superior to squared logs in its performance. By eliminating the natural wood faults through careful sorting of the boards, a more homogeneous construction material is formed with regard to appearance and strength.

The behavior of wooden girders in the event of fire is especially favorable. Through the formation of a charcoal layer on the surface, the center of the girder is protected from further rapid attack by the fire and is thus insulated. Therefore, the desired extent of fire resistance can be determined only by the corresponding dimensioning of the load-bearing beam.

Unlike steel girders, glulam girders have high rigidity. Treatment with preservatives is recommended as a surface protection for building components exposed to weathering to prevent attack by microorganisms.

Testing and Standards. To test glulam girders, European countries have agreed on standards that stipulate classification, strength requirements, and test procedures. Because of the economic importance of glulam beams, bondings based on amino and phenolic resins are continually controlled according to EN 301 and EN 302. EN 302.1 – 4 describes the following tests:

1) Determination of shear strength
2) Determination of resistance to delamination
3) Determination of the effect of temperature and moisture cycles on tensile strength (damage by acid)
4) Determination of the effect of shrinkage on shear stength

The results of these short-term tests are used to predict the long-term behavior of glulam girders. The effects of climate change and of cold and boiling water are determined. The boiling-water test showed that short-term tests do not always reflect the behavior of a gluing in outdoor weathering [37]. Tests according to ASTM D 1101 – 59 and D 905 – 49 show comparable results in the delamination test. Contraction of the adhesives during setting should be as small as possible; otherwise cracks occur in thicker glue lines, which are formed when the sections to be glued fit less exactly.

Tests carried out over many years [38] on the aging of wooden building components gave, for example, unsatisfactory results for brittle pure urea resin adhesives in the case of thick glue lines. Broad application of urea resins in building with wood was made possible only by using suitable extenders and fillers [39].

2.2.2. Veneers, Plywood, and Derived Products

2.2.2.1. Development

Veneers are thin sheets of wood obtained by sawing, cutting, or peeling. They are among the longest-known wood-based construction materials. The oldest archaeological finds originate from the heyday of ancient Egypt (ca. 3000 B.C.). Everyday and cult objects were decorated with inlays of different types of wood, known as marquetry. Because of their texture and color, veneers were initially used mainly for decorative purposes. However, composite constructions, consisting of a core of plywood with a veneer glued on to it, were soon recognized to warp less than pure wood boards. Since beautifully grained wood was rare and difficult to obtain even in antiquity and in the Middle Ages, veneers also offered the possibility of using wood sparingly [40].

2.2.2.2. Production of Veneers

Veneers are produced from cordwood or from specially divided blocks by using peeling and cutting machines or, less commonly, by sawing (Fig. 15). Many types of wood – e.g., poplar (*Populus* sp.), birch (*Betula* sp.), or Douglas fir (*Pseudotsuga* sp.) – can be peeled or cut either fresh or saturated with moisture through storage in water. Other types of wood – e.g., beech (*Fagus silvatica*), oak (*Quercus* sp.), ash (*Fraxinus* sp.), walnut (*Juglans* sp.), or various tropical high-density deciduous woods – must first be softened by steaming or boiling to alow the wood to be cut more easily.

After peeling, the veneers have a moisture content of 30 – 110 % (based on oven dry weight). This must therefore be reduced by drying to 4 – 12 % for further processing. Special veneer dryers are used through which hot air is blown at 80 – 200 °C.

2.2.2.3. Principal Types of Plywood

By combining veneers of different types of wood, densities, numbers of layers (plies), and different core materials, a large number of materials can be produced with widely differing properties and areas of use [41]. Plywood can be classified according to different criteria, frequently

according to its construction. EN 313 (see Section 2.2.2.6) differentiates among veneer, core, and composite plywood.

Veneer plywood normally consists of at least three layers of wood glued to one another crosswise. The barrier technique (orientation of the grain of adjacent layers at an angle, usually 90°) requires a symmetry around the middle layer with regard to type of wood, grain direction, and thickness of individual layers. By forming a barrier, the contraction in width of layers with longitudinal grain direction depends extensively on the mechanical deformation of transverse layers. At the same time, the strength and deformation properties in the longitudinal and transverse directions of the plies are aligned with one another, thus decreasing the anisotropy.

Plywood boards are thus considerably more dimensionally stable and can be subjected to loads more uniformly than solid wood boards. The number of veneers is usually uneven, and the arrangements are symmetrical. Three-, five-, and seven-fold boards, etc., are produced (Fig. 16).

Figure 16. Five-layer veneer plywood

Core Plywood. In core plywood (blockboard), the core consists of battens or strips, usually of light coniferous wood that has been cut from a block of boards or veneers that have been glued together and then blocked on both sides with veneers (Fig. 17). Depending on the core, two types of sandwich board exist: *battenboard* and *laminboard*. Wood core plywood is used for high-grade joinery.

Composite Plywood. Two types of composite plywood exist. In the first type the core consists of a material, usually of low density, that is planked on both sides with veneers. Practically any material can be used for the core (e.g., extruded particle board, paper honeycomb, and for special applications, polyurethane foam). These types of boards are used, for example, for doors and partitions. In the reverse case, the core can be made of plywood and the covering of metal sheeting or glass-fiber-reinforced plastic. The possible combinations are endless. Composite materials with special properties, such as high strength, good insulating capacity, and high abrasion resistance, can be produced for particular applications (e.g., containers).

Figure 17. Core plywood

Particular Laminated Materials. *Glulam boards* consist of three or more layers of wood sheets that are glued together crosswise. The thickness of the layers is at least 8 mm. These boards are used as shuttering panels and to an increasing extent as furniture panels.

In *laminated veneer lumber*, the veneers are glued together in the direction of the fibers. This allows the high longitudinal tensile and flexural strengths of the solid wood to be retained. If the veneers used for producing laminated wood are impregnated with synthetic resins – mostly phenol – formaldehyde resins – and compressed under pressure, *densified laminated wood* with a density $>1000\,\mathrm{kg/m^3}$, is obtained. This is used mainly for technical purposes.

Molded plywood is formed when the plywood is molded by using appropriately shaped presses. It is used, for example, for chair backs and seats, furniture, wall paneling, and girder webs.

Wood-based construction materials that are used mainly in building are known in North America as *engineered wood* (see Section 2.2.2.7).

2.2.2.4. Adhesives and Additives

The natural adhesives used initially, such as protein adhesives (gluten, casein, soybean, and blood albumin adhesives), have disadvantages (low resistance to climate variations, sensitivity to attack by microorganisms, long pressing times, and sometimes highly complex processing). Since the 1930s they have been increasingly replaced by synthetic adhesives, and these are nowadays used almost exclusively. They include urea – formaldehyde (UF), melamine – formaldehyde (MF), and phenol – formaldehyde (PF) resins, as well as MUF or MUPF mixed condensates. The use envisaged and the cost determine the choice of adhesive. A detailed description of the chemistry and technology of wood adhesives can be found in [42].

Urea – Formaldehyde Resins. The most important adhesives for gluing wood are urea – formaldehyde resins. The use of UF resins to glue plywood was first described in 1929 [43]. Production of these wood adhesives has since developed enormously [44]. Urea – formaldehyde resins are used for adhesion of wood materials used in the interior and have limited resistance to moisture. They can be readily adapted to operational requirements through the nature and dosage of curing aids and additives. Ammonium salts (e.g., NH_4Cl) are generally used as curing aids. They lower the pH by reacting with formaldehyde. The rate of curing increases with increasing temperature and decreasing pH. The viscosity of the adhesive liquor is adapted to processing conditions by the addition of water, depending on the content of extenders and fillers. The pressing temperature is 80 – 120 °C.

Melamine – formaldehyde resins undergo a curing reaction analogous to that of UF resins. Melamine – formaldehyde resins are characterized by their high water resistance and colorless glue lines.

For cost reasons, however, pure MF resins are rarely employed in plywood production. Instead, MUF or MUPF mixed condensates are used when high weather resistance is required. Depending on the melamine content and the type of wood, adhesions for semiexterior or exterior applications are obtained.

Phenol – formaldehyde resins are generally cured by heating and also by a combination of heating and curing aids. Phenol – formaldehyde resins are less reactive than UF or MF resins. They therefore require higher pressing temperatures (115 – 140 °C). Curing of phenol – formaldehyde resins is more sensitive to wood moisture and to pressing conditions than curing with other adhesives. Their alkali content can have damaging effects, e.g., on subsequent surface treatment of veneered boards.

Poly(vinyl acetate) adhesives are mainly used for bonding and veneer jointing.

Extenders and Fillers. In plywood production, extenders and fillers are used together with the adhesives to avoid glue penetration during hot pressing. *Extenders* are finely ground products of organic origin that are capable of swelling and gelatinizing and thus act as adhesives themselves (e.g., starches and cereal and vegetable flours). They are generally used with UF resins at levels of 15 – 30 % or higher (extender plus water, based on the adhesive resin) to reduce the brittleness of the glue line and resin consumption.

Fillers do not produce their own adhesion. They are finely powdered materials (e.g., nut shell or olive stone flours) or minerals, such as kaolin or pulverized gypsum (lenzin) that can be swelled only slightly or not at all. Fillers are normally used with PF resins.

The addition of extenders and fillers can decrease the resistance of the adhesion to water and microorganisms. Mineral fillers also increase the wear on tools.

2.2.2.5. Production of Veneer Plywood

The main operations involved in the production of veneer plywood are preparation, assembly, application of adhesive, stacking coated veneers (sometimes prepressing), hot pressing,

conditioning, forming (sometimes sanding), and sometimes fault elimination.

The adhesive is generally applied by using two- or four-roll machines, by pouring using an adhesive curtain, or by melting an adhesive film. The coated veneers are stacked either manually or by machine. To make transportation easier and reduce stack height, coated veneer stacks are frequently precompressed in an unheated one-daylight press. Hot pressing occurs in one- or multi-daylight presses similar to those described in Section 2.3.1.5 but usually with a smaller size. Pressing conditions (temperature, time, and pressure) depend on the type of wood, the strength of the plywood, and the type of adhesive. Pressures of 0.6 – 2.5 N/mm^2 and temperatures of 80 – 140 °C are usually applied. After gluing and sometimes climatization, veneer plywood is sanded, cut to standard or ordered measurements, and graded according to quality.

2.2.2.6. Properties, Testing, and Uses

Standards. The properties and quality of the adhesion of plywood are laid down in most countries by standards and trademarks. The following standards are valid in Europe and the United States:

Europe	
Plywood	
Classification and terminology	EN 313 (Parts 1 and 2) 1991
Test methods and properties	EN 314 (Parts 1 and 2) 1991
United States	
Hardwood and decorative plywood	PS 51-71, NBS-1972
Plywood for construction and industrial uses	PS 1-74, NBS-1974
APA grade – trademarks, available from American Plywood Assoc. P.O. Box 117 000, Tacoma, Wash. 98411-0700	

Depending on the type of adhesive and the wood, a distinction is made between plywood for exterior and interior use; further classification is made for the following applications:

1) In dry areas, i.e., a normal indoor climate (interior)
2) In moist areas, i.e., with protection against direct weathering also suitable for outdoor climates (semiexterior)
3) For outdoor use, suitable for long-term weathering (exterior)

The combined tension and shear resistance is generally tested on appropriately shaped test objects. A further criterion for the quality of an adhesion is the nature of the fracture pattern (percentage of fracture in the wood). With good adhesion the break will occur not in the glue line but in the wood. Before the strength of adhesion is tested, the sample is pretreated depending on the type of bonding. Pretreatment normally involves storage under different conditions, e.g., in cold, warm, or boiling water with redrying, or cycle tests.

Properties. Veneer plywood is normally produced in thicknesses of 1 – 12 mm and as multiply boards wich thicknesses of 13 – 50 mm. Wood core plywood is available in thicknesses of 10 – 60 mm. The density of veneer plywood depends on the type of wood and the plywood construction (500 – 800 kg/m^3). Wood core plywood generally has a lower density (450 – 750 kg/m^3).

The *hygroscopic properties* of plywood correspond approximately to those of solid wood. For indoor uses, the equilibrium moisture level is between 8 and 12 %. The water absorption decreases as the number of veneer layers and glue lines increases.

Dimensional changes due to contraction and swelling are low in the surface direction because of the barrier technique. The changes correspond approximately to the values for solid wood in the longitudinal direction (0.005 – 0.01 % for changes in water content of 1 %). However, changes in thickness approach those of solid wood in the radial direction (0.012 – 0.019 % for changes in water content of 1 %) despite the adhesive layers.

The *strength properties* of veneer plywood depend mainly on those of the veneers lying parallel to the main line of stress and on the type of wood. Although in solid wood the modulus of elasticity at right angles to the fiber is only ca. 10 % of that in the fiber direction, the properties of veneer plywood approach isotropy as the number of layers increases. Star plywood has almost the same strength when stressed at any angle. The strength properties of a veneer plywood (DIN 68 705, part 3, 1968) are listed below:

Bulk density (at 12 % moisture content)	500 – 800 kg/m^3
Flexural modulus of elasticity	7000 – 12 000 N/mm^2
In the direction of the	
covering fibers (3 layers)	700 – 1200 N/mm^2
(5 layers or more)	3000 – 7000 N/mm^2

Uses. Most of the plywood produced is used in building. Douglas fir and pine are used predominantly worldwide. Geographically, the consumption of plywood varies widely and depends mainly on local building traditions. Countries such as Canada and the United States are the largest plywood consumers worldwide, with 105 and 77 m^3 per 1000 inhabitants, respectively. In Europe, the Netherlands is the leading consumer, with 28 m^3 per 1000 inhabitants; in Germany, consumption is only 12 m^3, and in Italy only 6 m^3 per 1000 inhabitants [45].

Typical uses for veneer plywood are as construction plywood for wall, floor, and ceiling panels and also as panels for concrete shuttering. Industrial plywood is used to build railway coaches (e.g., for high-speed trains). A large area of use is in containers, boxes, and packagings. Plywood with decorative covering veneers is frequently used in interior furnishings (e.g., wall panels or doors).

2.2.2.7. Engineered Wood

The term engineered wood is used predominantly in North America and refers to wood-based construction materials, made by gluing together small-sized woods, that are used in building. The reason for this development is the increasing scarcity of suitably sized tree trunks.

Particles of small-sized wood and wood residues, such as flakes, strands, or parts of veneers, are combined by oriented agglomeration to give new wood-based construction materials using a method similar to that of particle board production. The properties of these materials are very similar to those of solid wood. Phenol – formaldehyde resins, amino resins (UF/MF), and polymeric methylene diphenylene isocyanate (PMDI) are used to glue the oriented wood pieces, which are mostly Douglas fir and pine.

By using 4-cm-wide and 12-cm-long strands, building materials of the most varying types can be produced in this way. They are known in the building industry as *laminated strand lumber* (LSL). The material is produced in the form of boards with thicknesses up to 14 cm, from which the desired building components can be cut (Fig. 18).

Figure 18. Laminated strand lumber

If strands with a thickness of ca. 3 mm and a length of ca. 250 mm (e.g., from peeled veneers) are glued in a parallel orientation, *parallel strand lumber* (PSL) is obtained. These beams can have a cross-section of 28 × 49 cm and are produced in a batch process in special presses in lengths of 20 m. Parallel strand lumber can be worked with normal tools and can be used like laminated wood (Fig. 19).

Gluing together peeled veneers with the fibers parallel gives *laminated veneer lumber* (LVL). In principle, this corresponds to veneered laminated wood. LVL is produced in lengths of 20 m and thicknesses up to 9 cm. The thickness of the veneers used is 2 – 5 mm (Fig. 20).

Trade Names. These building materials are sold in North America under the commercial names Intrallam (LSL), Parallam (PSL), and Microllam by Trus Joist International Inc. and Mac-Millen Bloedel Ltd.

Figure 19. Parallel strand lumber

Figure 20. Laminated veneer lumber

2.3. Particle Bonding

To overcome the pronounced anisotropy of solid wood, it must be cut up into small pieces; then the pieces can be oriented to a desired fiber direction. The following wood-based particles have achieved economic importance in the production of wood-based construction materials:

1) Chips for defibration and grinding
2) Shavings from cutting, peeling, and sawing
3) Strands
4) Wafers or flakes
5) Fibers
6) Wood wool

In industrial production, these particles are formed in a certain distribution with regard to dimension and shape. In practice, therefore, they must be sieved or classified. After drying and application of adhesive, the properties of the wood-based construction material can be influenced by targeted orientation of the particles during mat forming and by molding.

2.3.1. Particle Board

2.3.1.1. Development

In 1902, Henry Watson of Indiana had the idea of making particle board from waste wood. Unfortunately, no adhesives available at this time could allow industrial realization of this idea.

Only when the chemical industry made a suitable adhesive system available with the development of amino resins, could the industrial production of particle board be begun in Germany in 1941. After the end of World War II, the development of particle board technology made rapid advances in Germany and subsequently in the whole of Europe. Important contributions came from the Swiss F. Fahrni and the German W. Klauditz. In 1991, particle board was the most important industrially produced wood-based construction material, with an annual worldwide production of ca. 50×10^6 m^3.

2.3.1.2. Types of Particle Board

Flat Pressed Particle Board. In flat pressed particle board, the particles are arranged predominantly parallel to the board surface and bonded. Most of the particle board produced worldwide belongs to this group. The wafer, flake, and strand boards and oriented structural boards (OSB) produced widely in North America are, in principle, flat pressed particle boards. Although *wafer* and *flake boards* are made up predominantly of (decorative) wood particles with large surfaces and a thickness up to 0.02 inch (ca. 0.05 cm), *strand boards* are made from strands with a high ratio of slenderness having a thickness up to 0.2 inch (ca. 0.5 cm) and a length of 3 – 6 inches (ca. 7.6 – 15 cm). The production, transport, gluing, and matforming of these particles require special machines.

Figure 21. Different texture of flat pressed (A) and extruded particle board (B)

Extruded Particle Board. These boards are produced by extrusion. The process was developed in the 1960s by O. Kreibaum [46] and is still termed Okal process. Particles are arranged predominantly at right angles to the board surface. Short particles or granulated wood are mainly used. Adhesive-coated particles arrive in portions in the heated press, are compressed by using a pressure piston driven by an eccentric flywheel, and are extruded through the hot zone of the press. A continuous band of board is formed as it leaves the press. Heating of the board is accelerated by heated rods that project into the press. The heated rods themselves form tube-shaped hollows in the board. Extruded particle board is generally used only in the planked or veneered state because of the low flexural strength resulting from the production process. The production of profiles constitutes a further variant of the extrusion process. Figure 21 shows the difference in texture between flat pressed and extruded particle board.

Molded Objects. The production of molded particle board was described in 1948 in a Swedish patent [47]. In the same year, work began on the Thermodyne process, in which natural wood constituents are activated as binders at pressing temperatures up to 290 °C and pressures up to 300 bar [48]. The process was not successful economically because of the extreme operating conditions.

The process patented by the Werz company (Werzalite process) in 1956 uses wood particles containing 20 – 30 % amino resins [49]. These are compressed to form a blank and then prehardened. The blank is then coated immediately on all sides with paper impregnated with melamine resin. Operating conditions are very similar to those employed in particle board production. Production of molded objects using the Werzalite or similar processes was successful economically. Tabletops, window sills, paneling, palettes, and other molded objects are produced in this way.

2.3.1.3. Raw Materials

For particle board, low-value wood and industrial waste wood (e.g., remainders, slabs, splinters, and shavings from planing and sawing) are used. In countries with low indigenous wood production, the use of annuals such as cotton stalks, sugarcane bagasse, flax, rice husks, cereal straw, jute, esparto (alfa grass), and similar materials, instead of wood, is possible. These materials give a board that is very similar in properties to that made from wood [50].

In principle, all types of wood are suitable for making particle board. However, coniferous wood is used for most of the production in Europe and North America, which accounts for

75 % of the total worldwide particle board production. A combination of hard and soft types of wood is frequently used; the fact that these types of wood affect the properties of the board because of their differing sorption behavior is taken into account [51].

The time of wood harvest also affects sorption behavior and acidity, which in turn affect the curing of amino resins used to glue the particles. Some deciduous woods, such as oak or chestnut, have a high proportion of tannin and a low pH. Sometimes this impairs the strength produced by the gluing process. Wood bark used to be separated and incinerated or dumped, because the different structure of the bark generally required greater compression of the particles and the use of larger quantities of adhesive resins. Nowadays, however, the use of unpeeled wood has become common, even for the outer layer. Addition of 6 – 15 % bark to middle-layer particles does not affect board quality significantly [52]. Larger quantities of bark impair not only the appearance of the board, but also its strength and sorption properties. Excess bark in particle board factories is incinerated, and the waste gas is used for drying the particles [53].

Flat pressed particle board is now generally produced in several layers. The density of the individual layers and their construction determine the mechanical properties of the board. Light particle board has a density up to 500 kg/m^3. Most of the board produced is, however, in the density range of 600 – 800 kg/m^3. The thickness of the board ranges from 3 to 50 mm.

2.3.1.4. Adhesives and Additives

Amino Resins (UF, MF, and MUF). Urea – formaldehyde adhesive resins are used as 55 – 72 % aqueous solutions or as powders. For gluing particles, the resins now used predominantly have a basic U : F molar ratio of 1:1.0 to 1:1.3 to limit formaldehyde emissions. Catalysts based on ammonium salts or acids are used to accelerate the curing process. The use of resins with increasingly less formaldehyde finally led to a lowering of the cross-link density and thus to impaired quality of adhesion. This was corrected by reinforcing the UF resins with melamine [54]. To adhere to the strict limiting values for formaldehyde emissions in many countries, a special process for low-emission boards was developed by using reactive formaldehyde-rich resins and formaldehyde scavengers [55]. Urea – formaldehyde is used in quantities of 6 – 12 wt % solid resin, based on absolutely dry wood. UF-glued particle board is produced mainly for interior use and for furniture.

Higher-quality adhesions are achieved with melamine – formaldehyde, phenol – formaldehyde, or polyisocyanate resins. Because of their chemical similarity to UF resins, MF resins are mixed or cocondensed with them. Melamine – urea – formaldehyde and phenol-containing MUPF resins with 15 – 25 % melamine and up to 5 % phenol are used for particle board that is exposed to particularly high moisture levels. The dosage of resin is increased to 12 – 15 %, based on the dry wood particles.

Phenol – formaldehyde resins are high-value products, particularly because of their resistance to hydrolysis. They are used as aqueous alkaline solutions with a P : F molar ratio of 1:1.5 to 1:2.5. The alkali content is 3 – 10 %, depending on the degree of condensation of the resin. Phenol – formaldehyde resins are generally less reactive than amino resins. This means that, in practice, longer pressing times must be used for processing PF resins compared with amino resins. Alkaline phenolic resins dye particle board light brown and increase its hygroscopic nature. PF-glued particle board produces no significant formaldehyde emissions. It is used for exterior applications. The usual dosage of resin is 8 – 12 %.

Polymeric Methylene Diphenylene Isocyanate. Since 1980 adhesives based on PMDI have increasingly been used. They consist of a mixture of monomeric, polymeric, and oligomeric diisocyanates, which are capable of reacting with the cellulose, lignin, and moisture in wood. The quality of wood adhesions using PMDI is comparable to that using PF resins. A significant disadvantage of isocyanate adhesives is their tendency to stick to metals. PMDI can therefore not be used without release agents.

Handling PMDI adhesives requires particular care because of their high reactivity toward water and bases. However, they are very economical. Adequate board strengths are achieved with 3 – 5 % adhesive.

Adhesives Based on Natural Materials. Adhesives made from waste sulfite pulping liquor and from wood and bark extracts are known, but have not achieved great economic importance.

Mineral Binders. Special boards for building purposes are also produced using inorganic binders. These include Portland cement, magnesia cement (Sorel cement), and gypsum (see Section 2.3.3).

Additives. For repelling water and delaying swelling during particle board production with synthetic resins, 0.1 – 1.5 % paraffin, based on dry wood, is generally added. Paraffin is mixed with the adhesive liquor as a dispersion or applied to the particles as a finely dispersed melt.

2.3.1.5. Production

Particle Production. The wood to be milled should have a moisture level of ca. 50 % and be free of metallic or mineral substances. Low moisture levels increase the throughput of the size reduction machine, but also increase dust formation and fire hazards.

Chipping machines with very varying mechanisms are used for size reduction. For lengthwood (roundwood) machines with cutting tools fixed in a carrier disk or drum, together with spurs, are preferred. By pressing the wood onto the rotating blade carriers, uniformly thick particles are formed, which can be cut up further in a subsequent mill if desired. The most powerful chipping machines of this type are knife shaft machines with an operating width of 2 m. For making larger particles, knife ring machines are used, which have combined cutting and striking tools. To cut up the particles further, hammer, wing beater, and toothed disk mills are used. The target of the size reduction process is the production of a mixture of particles that are as uniform as possible in shape and thickness. The geometry of the particles affects both the further processing (distribution and dispersion of glue) and the mechanical properties of the board. Since particle board for use in surface coating is produced mainly in three or five layers, the aim of particle preparation is to produce different mixtures of particles. Fine particles for the outer and coarse ones for the middle layer are obtained by air classifying and screening. For particle board used in building, large proportions of fine particles and dust are undesirable.

Figure 22. Particle glue-blending machine EK-AB 50 (Loedige, Paderborn, Germany)

Drying. To process the particles further, residual moisture levels of 1 – 3 % are necessary. High moisture levels, together with the water applied with the adhesive resin, generally cause steam cracking in the pressing process. Drying the particles is therefore indispensable.

Drying follows the rules of convection drying. In the first part of the drying process, wood moisture decreases almost linearly. The second part of the drying process is determined by vapor diffusion.

With particles of varying thickness and size, uniform drying is difficult to achieve. Separate drying of the coarse middle-layer and fine outer-layer materials is therefore necessary. To dry the particles the following powerful machines are used: (1) jet dryers, (2) tubular dryers, (3) stream dryers, and (4) drum dryers.

Glue blending of the particles occurs continuously in flow mixers to achieve as uniform a distribution of the adhesive on the surface of the particles as possible. Dried particles are fed to the mixer via a belt weigher. The necessary quantity of adhesive is dosed volumetrically or gravimetrically with electronic control.

In the mixer, adhesive is rubbed on the surface of the particles or applied by using spray jets. The efficiency of the mixer depends on the design of the mixing drum and the conveying

and braking tools. Because of the heat of friction produced, the mixing vessel must be cooled with water. Figure 22 shows a high-performance mixer from the Loedige company.

Forming Mats. Glue-blended particles are fed from the storage hopper into the dosing hopper of the forming station by using conveyor screws or belts.

By controlling the volume of the glued chips a uniform flow of particles is produced, which is deposited onto a moving forming belt via a toothed feed roller. The falling particles receive an impulse from a spreading roller, resulting in separation of the coarse and fine particles. Commonly, the mat is formed by using air classifying. In this process, air is blown against a curtain of falling particles so that fine particles are carried further with the air than coarse ones. Here also, classified particles fall onto a conveyor belt below. With two blowers set opposite one another, mats can be formed that have coarse particles in the center and finer particles on the outside. For reducing thickness, the mats are precompressed in a cold press and then passed to a hot press for activation of the adhesive.

Pressing and Pressing Techniques. In hot pressing the blank is compressed to the desired final thickness and the adhesive is irreversibly cured. Both continuously operating and batch presses are used.

Batch Presses. The output of presses for batch processing is limited by the pressing and cycle times. With *one-daylight* presses, high

pressing temperatures (200 – 230 °C) are used to shorten the setting time of the adhesive. *Multi-daylight presses* have up to 20 daylights and are operated at < 200 °C. Automatic charging and emptying of a multi-daylight press require complex machinery. The tolerance in thickness of the boards produced by using the batch press is so great that calibration by sanding is indispensable.

Continuously Operating Presses. In larger particle board plants, continuously operating presses are mainly used. With this technique, boards are produced with significantly smaller variations in thickness than in batch production. Various continuously operating systems exist.

Roller Presses. In roller presses the application of pressure and transportation is effected by a bed of rods. Figure 23 shows a ContiRoll plant of the Siempelkamp company, as a typical example of this type of machine. Pressure and temperature control in the ContiRoll process is illustrated in Figure 24. Figure 25 shows how the pressure is conferred by means of the bed of rods. The operating temperature is 220 – 250 °C. Continuously operating roller presses are usually designed for capacities of more than 400 m^3 of board per day. The production costs are up to 8 % less than those for batch presses because of the lower energy consumption.

Figure 25. Moving rod system of the ContiRoll press
a) Bed of rolls; b) Steel belt; c) Mat

Gliding Film Presses. In gliding film presses the pressure is transmitted by an oil film (Hydro Dyn process of the Bison company) or by air cushions (Hymmen company).

Calender Presses. In calender presses pressure is applied to the blank by pressing it with steel bands on a heated cylinder (calender). Figure 26 shows a calender press that operates using the Mende process (producer Bison). The system is particularly suitable for producing thin particle board.

Extrusion Presses. In extrusion presses the particles are extruded continuously between heated plates or rods (Okal process, see page 26). Profiles and tubular boards are produced by this method.

Steam Injection Presses. Heating the mats can be accelerated by using steam injection presses. The steam is injected immediately before pressure is applied. The process is particularly suitable for thick boards, which are difficult to heat through. Since 1989, it is being developed further by Siempelkamp.

To *heat the presses* a heat-transfer oil is used predominantly as the energy carrier. Experience with the use of high-frequency energy is extensive. For cost reasons, it is now used only for warming the mats in prepresses.

The *pressing time* necessary is determined by the reactivity of the adhesive system and the pressing temperature. The specific pressure of 20 – 50 bar is decreased in steps as the spring back forces of the compressed mat decrease and the adhesive takes effect (Fig. 24).

Aftertreatment. After hot pressing, particle board is cooled and conditioned by storage for several days. This process leads to further setting of the adhesive so that the internal bonding of the board increases and the thickness swelling values decrease. The board is standardized by sanding.

2.3.1.6. Properties, Testing, and Uses

Properties. Even in glued particle board the hygroscopic properties of the basic material, wood, are noticeable. The state of equilibrium between the moisture in the wood and the relative air humidity causes ad- and desorption of water on climate change, which, in turn, lead to a change in volume. The properties of particle board are determined by the orientation of the particles, which depends on the process used. This effect is most obvious in the case of extruded and flat pressed particle boards (see Fig. 21). Even in flat pressed particle board the longitudinal and thickness-sectional swelling

Figure 26. Calender press for thin particle board production (Bison, Germany)

differ by a factor of 10. The swelling and shrinkage behavior of particle board is also determined by the intensity of compression of the particles (board density), the nature and quantity of the adhesive, and the type and quality of the wood. Changing properties by altering wood quality is becoming less and less feasible because of the continually increasing use of residual and waste wood.

For mass production of boards in the furniture industry, dimensional stability is extremely important. Assessment criteria are the absorption of moisture and the swelling in moist air and on storage underwater. The sorption test in moist air and determination of the swelling after storage underwater do not always give the same results [56] since the final swelling is not achieved as rapidly in short-term storage underwater because of the delay in water absorption due to high board density or the use of a hydrophobing agent (paraffin).

Figure 27 shows the longitudinal and thickness swelling and the water absorption of flat pressed particle board based on spruce and glued with UF resin on storage in moist air (95 % R.H.).

Mechanical properties are adapted to the use envisaged as much as possible. The strength perpendicular to the board surface (*cross tensile strength*) is an indication of the quality of the bonding. It can be influenced by the nature and quantity of the adhesive, its distribution on the particles, and the compression of the board.

The *flexural strength* (i.e., bending strength) of the board is particularly important for use in building. It can be improved by orientation of the particles (OSB) in composite board. Generally, the outer layer is more highly compressed than the central layer so flexural strength can be influenced by the sandwich effect (low-density core- and high-density toplayers).

The strength properties depend on hygroscopic properties. Figure 28 shows the impairment of flexural and cross tensile strengths by moisture absorption on storage in water.

Testing. Many selective procedures are used to test the chemical, physical, and biological resistance of particle board [57].

Europe is the area with the highest particle board production. Here, efforts have been made to harmonize the standard requirements and tests. In EN 312, parts 1 – 7, the requirements are *classified* according to areas of use. In the United States, a differentiation is made between interior and exterior use in commercial standards CS 236. In the Japanese Industrial Standard JISA 5908, boards are classified according to their flexural strengths.

To assess *formaldehyde emissions* the desiccator test is used predominantly in the United States and Japan, while the perforator and gas analysis tests (EN 129 and EN 717) are used in Europe. Large test chambers are used in different countries to measure formaldehyde equilibrium concentrations, to give a reference value for the short-term emission test. For the corresponding European standard, operating conditions for a large testing chamber have not yet been laid down. In the United States, ASTM E 1333 is followed.

Resistance of the adhesions to *climate rotation* is determined by the short-term aging tests described in ASTM D 1037 and EN 321. By using a multistage cyclic test, involving storage in water, evaporation, action of frost, evaporation, and drying, the adhesions, in particular, are assumed to be exposed to aging. Also, boiling the test object in water for several hours according

a) Transverse tensile strength; b) Flexural strength

to DIN 68 763 (V 100) gives information on the resistance of adhesions.

Particle board for use in building often has high resistance to *biological decomposition* by microorganisms as well as high-quality adhesion (ASTM D 1413 and EN 335-3).

Widely differing test procedures are used to assess the *flammability* of particle board. Flame propagation, smoke development, and calorific value are determined according to ASTM E 84. In Germany, according to DIN 4102-8, in particular, the length of the test piece that remains undamaged is measured. British Standard BS 476-6 uses an index which is calculated from the temperature of the combustion gases.

2.3.2. Fiberboard

2.3.2.1. Development

Fiberboard consists, like paper, of lignocellulose-containing fibers. Both materials are related with regard to production and construction, and the history of fiberboard is closely associated with that of pulp and paper.

The first fiberboard was *softboard* (an insulating board). It was produced in the United Kingdom at the turn of the century – and somewhat later in the United States – from waste fibers that were unsuitable for paper production because they were too short. *Hardboard* was developed in the United States in the 1920s to utilize sawmill waste.

The production of fibers from chips is similar for all fiberboard production processes. The middle lamellae binding the fibers, which are rich in lignin, are softened by heat and moisture, and the fibers are then separated mechanically.

An important discovery was made by H. Mason, who developed the Mason cannon in 1926. In his process, the chips are first softened in a boiler under high pressure. This is followed by a sudden pressure release accompanied by a loud cracking sound, which indicates breakdown of the wood structure into fibers and bundles of fibers. These are pressed in a hot press to form hardboard without the addition of binders.

The Swede A. Asplund made the pioneering discovery of the *defibrator* in 1931. In the Asplund process chips that have been softened by steam are broken down into fibers by grinding between two disks.

The first hardboard was produced, like paper, by the *wet process* from a thin aqueous fiber suspension. The fiber mat transported to the hot press contained so much water that sieves were necessary for draining. The imprint of the sieve remains on the underside of the finished hardboard. Hence, this type of board is also known as *S1 S* (*smooth one side*).

The sieve imprint was undesirable for many applications. A board was subsequently developed that was smooth on both sides (*S2S, smooth two sides*). In this case, softboard is produced that is then compressed to hardboard between two smooth pressure plates.

Wet processes require enormous quantities of water. Pollutants, such as extractives, hemicelluloses, and lignin, are present in the wastewater. For environmental reasons the *dry process* was developed. Here, the fibers are dried, glue-blended, and pressed as in particle board production. This process gives an S2S board. For reasons of surface quality, gluing is carried out before drying. The *semidry* process lies between the wet and dry processes. Because fiber moisture is still present, sieves must be used and S1S board is produced.

2.3.2.2. Types of Fiberboard

The classification and nomenclature of the different types of fiberboard on the market seem confusing because the names either have a historic origin or represent current types of board or properties [58]. An overview is given in Table 8. Two important criteria used in classification are the production process and the board density.

Wet Process. The following types of board are produced by the wet process (S1S, density $> 800\,kg/m^3$); tempered hardboard with higher strength and water resistance (density $> 960\,kg/m^3$, thickness 2.5 – 5.0 mm); two types of mediumboard: low density ($350 - 560\,kg/m^3$) and high density ($560 - 800\,kg/m^3$); and softboard.

The density of softboard is $< 350\,kg/m^3$ (thickness 8 – 16 mm). Impregnated softboard is treated with bitumen or other additives to increase its water resistance (density up to $400\,kg/m^3$).

Table 8. Classification of types of fiberboard

Process	Board specification	Surface	Density, kg/m^3	Notes
Wet	standard hardboard	S1S	>800	
	tempered hardboard	S1S	>960	higher strength and water resistance
	low-density mediumboard	S1S	350 – 560	
	high-density mediumboard	S1S	560 – 800	
	softboard (insulationboard)		≤ 350	higher water resistance
	impregnated softboard		≤ 400	
Semidry	semidry process hardboard	S1S		
Dry	dry process hardboard	S2S	800 – 1000	adhesive PF
	medium-density fiberboard (MDF)	S2S	600 – 850	adhesive usually UF, occasionally PF or PMDI, thickness <4 mm
	low-density fiberboard	S2S	450 – 600	
	high-density fiberboard (HDF)	S2S	800 – 1000	
	MDF specialities			
	moisture resistant			
	exterior			
	flame and fire retardant			

Dry Process. Dry process hardboard is an S2S board that is normally produced by using PF resins (density 800 – 1100 kg/m^3). Medium-density fiberboard is generally produced by using UF resins (density 600 – 840 kg/m^3). Other types of fiberboard are, e.g., low-density board (450 – 600 kg/m^3); high-density fiberboard (800 – 1000 kg/m^3, thickness <4 mm); and moisture-resistant, exterior, and flame- and fire-retardant fiberboard.

Plasterboard. Besides the classical wood-based fiberboards, a fiberboard bonded with gypsum is becoming increasingly popular for use in interior furnishing for partitions and panels. Plasterboard can be produced from waste paper and gypsum from the desulfurization of exhaust gases. The production process is similar to that used for wood particle board using mineral binders (see Section 2.3.3.2).

2.3.2.3. Raw Materials

Fiberboard can be produced from all lignocellulose-containing materials with industrially utilizable fibers. However, for reasons of availability, wood is almost always used. To minimize variations in the process, only one type or a very limited number of types of wood are employed, the latter as a mixture of constant composition.

Deciduous and coniferous woods differ in their anatomical construction (see Section 1.2). Coniferous wood fibers are generally two to three times as long as those of deciduous wood (Fig. 29). The importance of the properties of the raw materials and fibers for the production process and for board quality is discussed in detail in [59]. Unlike paper, in fiberboard the fiber length is relatively unimportant. However, to a certain extent it determines the orientation of fibers in the board. Short fibers tend to be arranged vertically and longer ones horizontally. Fibers with thin walls nestle together better in the press than those with thick walls. The density of the wood used determines the thickness of the fiber mat. The lower the density, the thicker the mat, and consequently the higher are the degree of compression, the contact between fibers, and the resulting strength of the board. Dry processes are generally less sensitive to the properties of wood than wet ones. In the wet process, deciduous woods give better hardboard and coniferous woods better softboard. Coniferous woods require longer steaming times and, therefore, more energy for fiber production than deciduous woods. Mixtures of deciduous woods are mostly available in groups classified according to density. The lower the density of the deciduous wood, the longer is the digestion time. For cost reasons, efforts are made to use waste wood instead of roundwood as far as possible. Debarked chips from sawmills give good fiberboard.

Sawdust is less suitable because of the irregular particle sizes and short fibers; it requires expensive preparation. Bark is not suitable because of its mineral components and dark color. Of the lignocellulose-containing annuals, only sugar-

cane bagasse is important for softboard production.

Figure 29. Wood fibers for MDF production
A) Deciduous wood; B) Coniferous wood

2.3.2.4. Binders and Additives

In the production of fiberboard by the wet process, no binders are required in principle because of the binding forces already present in the wood. However, adhesives are necessary for the dry process. Table 9 gives an overview of the main types of fiber bonding.

Table 9. Types of fiber bonding and additives used in fiberboard production, according to [59]

Process	Board type	Main binder	Auxiliary binders
Wet	insulationboard	hydrogen bonds	asphalt, starch
	S1S	lignin	PF, drying oils
	S2S, MDF	lignin	rosin
Dry	S2S	PF	
	MDF	UF, MUF, PF, PMDI	

The main purpose of additives is to improve the mechanical properties and water resistance of fiberboard. In *softboard* the fibers are bonded predominantly by hydrogen bonds. For hydrophobing, molten paraffin (ca. 1 % slack wax based on dry fiber) or asphalt emulsion is added. For *hardboard*, lignin, which is activated in the hot press, is the important binder.

S1S board is produced mainly with the addition of highly condensed, alkaline PF resins (0.5 – 2.0 % based on dry fiber), which are fixed on the fiber by the addition of $Al_2(SO_4)_3$. Paraffin (0.1 – 0.5 % based on dry fiber) and drying oils, such as linseed oil, are also added.

For *S2S board produced by the wet process*, phenolic resins cannot be used because the severe drying conditions would result in premature curing. Resins such as rosin are therefore employed. They are fixed on the fiber by lowering the pH with $Al_2(SO_4)_3$.

S2S dry process hardboard is generally produced by using PF resins (ca. 6 % based on dry fiber). For *MDF produced by the dry process*, UF resins, generally modified with melamine, are the most important binders (10 – 14 % solid resin based on dry fiber). To a small extent, mainly for special boards, MUF, PF, and PMDI are used. As with S2S boards, paraffin is used for hydrophobing.

2.3.2.5. Production Processes

Raw material processing and fiber production in the wet and dry processes are very similar, frequently even identical.

Raw Material Processing. The wood used is predominantly roundwood, also partly debarked chips from sawmills or whole-tree chips. Pieces of bark are generally undesirable. They contain minerals that shorten the service life of refiner disks and processing tools, and impair surface quality.

Roundwood is generally debarked before chip production. This can be carried out by using ring or drum debarkers.

Chips are most frequently produced by using disk chippers or cylinder chopping machines. The cutting disk of the disk chipper, arranged vertically or diagonally, is fitted with 4 – 16 blades, depending on the size. The positions of the blades determine the dimensions of the chips.

Fine chips (< 4-mm sieve mesh) and coarse chips (> 40-mm sieve mesh) are separated from normal chips by sieving on flat or drum sifters. The fine chips are incinerated, and the coarse ones are cut up further in hammer or wing beater mills. The optimum chip size is 20 – 25 mm × 20 mm × 5 mm.

To remove foreign material and mineral components, chips are washed before further processing. This is particularly important with

whole-tree chips. Washing is carried out in specially designed plants with prewashers for separating coarse components and a screw drainer for separating fine mineral particles. The chips are then stored in reinforced concrete or metal silos. Storage acts as a buffer between chip and fiber production and at the same time allows the moisture distribution to become more uniform.

Table 10. Processes for fiber production

Process (company)	Type of defibration	Conditions
Masonite (Masonite)	Mason cannon	1) 30 – 40 s steaming at 24 bar (220 °C) 2) 2 – 3 s steaming at 69 bar (280 °C) 3) explosive pressure release
Asplund (Sunds)	defibrator (one rotating grinding disk)	2 – 5 min steaming at 6 – 12 bar (160 – 195 °C) in preheater
Bauer (Sprout – Bauer)	Bauer refiner (two counterrotating grinding disks)	3 – 10 min steaming at 3 – 8 bar in the Bauer digester

Fiber Production. The aim of defibration is to break up the previously chopped raw material as carefully as possible into individual fibers and bundles of fibers. This is carried out thermomechanically. The lignin-rich middle lamellae that bind the fibers are first softened by heat and steam. The fibers are then separated by mechanical abrasion. They are often broken in the process, giving fiber fragments. The anatomical nature of the fibers and their state after defibration are important for forming the fiber mat and for the properties of the board. This applies particularly to the wet process in which the freeness (draining behavior) and the type of matting are very important.

Thermal treatment of the chips before and during defibration causes part of the hemicelluloses to go into solution. Increasing the temperature and the length of the treatment period leads to increased softening of the interfiber bonding. In the wet process, this improves the natural adhesion between fibers during board production. At the same time, the sugar content of the wastewater and the energy consumption increase, so that a compromise between environmentally friendly and economic process design and board properties is usually aimed at. Fiber production is energy intensive; it consumes more than half of the total process energy. Table 10 gives an overview of important current fiber production processes.

In the *Masonite process*, both the softening of fiber bonds and the separation of fibers are effected by steam. This technique is used exclusively in the United States by the Masonite company (wet process).

Refiners. In all other processes defibration is carried out by using grinding disks. Some defibrators operate at atmospheric and others at elevated pressure. Also, machines exist with only one rotating grinding disk (Sunds) or with two counterrotatory disks (Sprout-Bauer). Refiners operating at atmospheric pressure have the disadvantages of high energy consumption and moderate quality of the fibers produced.

The refiner now used predominantly, which operates under pressure, gives better results. The Asplund defibrator (Sunds) is a prototype. This makes use of the fact that from ca. 170 °C, separation of fibers in the middle lamella is considerably easier and is associated with a significant lowering of the energy consumption and an improvement in fiber quality.

In the defibration process (see Fig. 30), washed chips are fed into the preheater through a conical opening using a screw feeder (c). The preheater (e) is usually a vertical, slightly conical pressure container, which is continuously charged with saturated steam at 150 – 180 °C. The steam heats the chips by condensation. Blowing steam out through the opening is hindered by the plug formed in it by the chips (d).

In 1 – 3 min the chips reach a conveyor screw (g) at the base of the preheater through which they are transferred to the grinding disks of the refiner (h), where defibration takes place under steam pressure. The necessary grinding power is ca. 200 kW per tonne of dry fiber.

The important parameters affecting the quality of the fiber material and the energy consumption are the residence time and vapor pressure in the preheater, throughput quantity, defibrating pressure, distance between grinding disks (0.1 – 0.4 mm), number of revolutions per minute, state of the grinding disk, nature of the raw material, and moisture level.

Defibration is tested by determining the degree of grinding or by fractionating the fiber material. The degree of grinding is a measure of the freeness of the fiber material and determined by means of the dewatering speed of a fiber

Figure 30. Asplund defibrator continuous pulping plant for fiberboard
a) Chip chute; b) Vibratory; c) Screw feeder; d) Chip plug; e) Preheater; f) Gamma-ray level controller; g) Conveyor screw; h) Asplund defibrator

suspension (standard freeness tester, defibrator-seconds, DS). In the wet process, higher degrees of grinding usually result in an improvement in board properties.

After defibration fibers are blown out through a pressure-regulated exit valve. From this stage onward the wet and dry processes differ and are described separately below.

Wet Process. A fiberboard production plant using the wet process is shown schematically in Figure 31. The fiber material is fed to silos (b) for mixing and adjusting concentration (4 – 6 %) or is further defibrated in disk refiners (f). For hard and semihard fiberboards a degree of grinding of 18 – 30 DS is aimed at, and for porous boards 42 – 70 DS [60].

A system of tanks and conveying devices is used for mixing, storing, and addition of adhesives and additives (see Section 2.3.2.4). A control panel connected to the system regulates concentration, temperature, and pH.

The fiber mat is formed on a sieve by drainage of water from the fiber suspension and subsequent sedimentation of the fibers. Mat formation was previously carried out as a batch process in tanks, but cylinder wet machines and conveyor sieve dewatering machines are predominantly used now. The main component of the latter is a continuously moving sieve. Fiber material is added through a headbox at a concentration of 1 – 2 % and is subsequently drained and compressed by means of a forming table, suction box, and wet pressing section.

To improve the surface properties of the smooth side of the fiberboard, fiber material of higher quality can be applied to the mat on the forming table through a second headbox. After the wet press the thickness of the mat is 20 –25 mm, which gives a final thickness of 3 – 5 mm. The mat is then separated into individual sections corresponding to the pressed board format of the hot press.

In the production of *softboard* or *S2S hardboard* by the wet process, the drained fiber mats are dried in single- or multideck dryers at 150 – 170 °C from moisture levels of 100 – 120 % to 1 – 4 %.

To prevent dried boards from catching fire during subsequent storage, they are cooled immediately after drying by spraying with water and aspiration of ambient air.

S1S board is further dewatered in hydraulic multi-daylight presses by hot pressing using

Figure 31. Schematic of fiberboard production by the wet process

an established pressure – time program, compressed, and strengthened by curing the binders that are naturally present or have been added. For S1S, use of a draining sieve is necessary to remove the large quantities of water. For hardboard the pressing time is generally 2.0 – 3.5 min/mm at a pressing temperature of 180 – 200 °C. A typical pressing diagram consists of three phases, the compression and first high-pressure stage, drying, and the second high-pressure stage.

An improvement in the properties of fiberboard can be effected by thermal aftertreatment in chambers or continuously in tunnels or by impregnating with drying oils (see Section 2.3.2.4). Treatment results in a more uniform moisture distribution in the board as well as better dimensional stability.

Dry Process. The production of MDF is shown schematically in Figure 32. After defibration (g) the fibers pass down a blow line in which glue (see Section 2.3.2.4) is added and then reach the fiber dryer (i). Alternatively, they can be blown directly into the fiber dryer (i) by making use of the vapor pressure present in the refiner. In this case they are subsequently glue-blended in high-speed centrifugal machines, as in particle board production. In almost all plants, glue blending occurs before drying, thus avoiding spots of adhesive on the board surface that impair its quality. Paraffin added to improve hydrophobic properties is generally charged in the molten state to the lower conveyor screw of the refiner.

Tube dryers are now used exclusively for drying the fibers. They are mostly two-stage dryers with tube lengths of 80 – 100 m and diameters of 1.3 – 1.6 m. The air temperature at the entry is 140 – 170 °C. Because of the high air speed (ca. 30 m/s) and the small dimensions of the fibers, the drying time is only a few seconds [61]. The moisture level of the fibers is adjusted to 9 – 11 % by regulating the exit temperature of the dryer.

The fibers reach the forming station (m) via cyclones and fiber hoppers (j). The fiber mat is formed either mechanically by using a snowfall felter or pneumatically by using a pendistor on a vacuum screen conveyor.

The uniformity of distribution of the fiber material over the surface of the screen significantly affects fiberboard properties.

The mat coming out of the forming station has a very low bulk density and contains a large quantity of air, which must be removed before hot pressing. To decrease the size of the press opening, shorten the closing times of the hot press, and improve the transportability of the mat and the surface quality of the finished board, the mat is precompressed in continuously operating belt prepresses. Mat density is thus doubled or trebled.

Hot pressing of the fiber mat occurs either batchwise on multi-daylight presses with preliminary separation into mat sheets or, as is now increasingly common, continuously on double-belt presses or calenders for thin boards (up to 8-mm thickness). The presses are the same as those used for particle board production (see Section 2.3.1.5). To heat the fiber mat more rapidly and shorten the pressing time, the fiber mat is often subjected to high-frequency preheating before entering the hot press. Pressure control in MDF production differs from that in particle board production. Figure 33 gives an example of the pressure program.

The bulk density profile (perpendicular to the board thickness) and thus the properties of the board can be widely varied through the type of compression and the temperature control. High compression in the outer zones and as uniform a density as possible in the inner zones are aimed at (see Section 2.3.2.6).

2.3.2.6. Properties, Testing, and Uses

Properties. The main factor affecting almost all properties of fiberboard is its *bulk density*. This determines the flexural strength and modulus of elasticity, and affects the transverse tensile strength and swelling properties. Besides bulk density, the bulk density profile perpendicular to the board thickness is most important in the case of MDF. S1S hardboard produced by the wet process has a highly compressed upper side and a less dense underside (sieve side). S2S boards formed by the wet process have a symmetrical density profile with a minimum in the center of the board and maxima at a certain distance from the board surface. This gives the boards high flexural strength [59].

Figure 33. Pressure program for MDF production (Siempelkamp, Germany)

Figure 34. Examples of density profiles of MDF
a) High density contrast; b) Low density contrast at the same average density

Figure 34 shows two different density profiles of MDF board. Highly compressed outer zones with a high density relative to the center, and the resulting high flexural strength and low transverse tensile strength, are achieved by closing the press rapidly. A more uniform density distribution with smaller density differences between the outer and middle layers, lower flexural strength, and higher transverse tensile strength is achieved by closing the press slowly [62]. In practice, a compromise between the two extremes is usually aimed at.

Figure 35. Comparison of density (A), Flexural strength (B) and transverse tensile strength (C) for wood-based construction materials

Quality requirements and test methods for fiberboard are laid down in a large number of international standards. The standards for the United States and the EC are given below.

United States	
Insulationboard	ANSI/AHA A 194.1 – 1985
Basic hardboard	ANSI/AHA A 135.4 – 1982
Prefinished hardboard	ANSI/AHA A 135.5 – 1988
Hardboard siding	ANSI/AHA A 135.6 – 1989
MDF	ANSI/AHA A 208.2 – 1990
EC	
MDF, Industry Standard	Euro MDF Board (EMB) (Gießen – 1990)
Fiberboards (dry process)	EN 622 – 1993

Within the framework of production monitoring and quality assurance, the following fiberboard properties are generally tested:

1) Tensile strength perpendicular to the board surface, either dry or after the wet cyclic test
2) Flexural strength and flexural modulus of elasticity
3) Swelling after 24 h or after the wet cyclic test
4) Formaldehyde emission

The following properties are tested less frequently: screw withdrawal, dimensional stability, sand content, and surface absorption.

A comparison of the strength properties of hardboard and MDF with those of solid wood and particle board is given in Figure 35. The advantages and disadvantages of MDF compared with particle board, veneer plywood, and table board are given in Table 11.

Table 11 shows that MDF does not have any advantages over particle board with a fine covering layer with regard to finishing by veneering, laminating, and liquid coating. However, in all further processing in which the homogeneous fine fiber structure in the interior of the board is utilized, MDF has advantages over the other types of board. The edges can be milled, polished, and coated.

Uses. The main areas of use for fiberboard are as follows:

Insulationboard is used in interior and exterior applications, mostly as parts of walls, and for ceiling paneling, frequently in the form of accoustic panels.

Hardboard produced by the wet process generally consists of thin boards. It is employed mainly in buildings for inner and outer wall paneling. It is also used in the production of furniture or doors or molded for use in motor vehicle interiors.

MDF. Because of its excellent edge and surface properties and its good workability, MDF is used mainly for furniture production.

2.3.3. Wood-Based Materials with Mineral Binders

Wood-based materials with mineral binders consist of 30 – 90 % of a hardened inorganic binder and 10 – 70 % of wood particles. Because of the high binder content, these materials are heavy and particularly suitable for use in building. The most important mineral binders are cement, gypsum, and magnesia (magnesite) [64].

Mineral-bonded boards are characterized by low thickness swelling through the action of water. Cement- and magnesia-based boards are highly resistant to mold and termites [65]. Cement-bonded boards are used mainly for exterior applications because of their high resistance to weathering. All mineral-bonded wood-based construction materials are classified as building materials of low flammability because of their high binder content.

2.3.3.1. Cement-Bonded Boards

Cement was the first mineral binder used in the industrial production of boards. The originally long hardening times of this hydraulic binder have been shortened greatly by technical measures [66]. The setting time depends not only on the reactivity of a particular cement quality, but also on its compatibility with different types of wood. Wood components, such as free sugars, glucosides, and tannins, delay the hydration of cement and therefore impair the setting process [67]. Cement-bonded wood-based boards are produced predominantly by the wet or semidry processes.

The original production process developed by Elmendorf is still used in different forms [68]. In the process, wood particles, cement, additives, and water are mixed, molded, and compressed. To shorten the hardening times, stacked boards are fed into a heated tunnel under pressure. The boards can generally be removed from their molds after 6 – 8 h and then conditioned for 12 – 18 d in storage until the final strength is reached.

Finished boards consist of ca. 60 wt % cement and additives, ca. 20 wt % wood, and ca. 20 wt % water. The ratio of total water to cement determines board properties such as compressive and flexural strength.

2.3.3.2. Gypsum-Bonded Board

For many years, gypsum has been an indispensable building material. Since the actual strength of pure gypsum is insufficient for the production of board material, it is reinforced with wood fibers, wood wool, or flakes. The suitability of

gypsum as a binder is based on the de- and rehydration processes. The water of crystallization is partially removed from mined or industrially produced gypsum by calcination. In the setting process the water added becomes chemically bonded as water of crystallization. The quantity of water that is necessary for complete rehydration depends on the quality of the gypsum and is generally 14 – 21 %. Excess water is not bonded and must be removed from the system.

Wet Production Process. In the production of plasterboard by the wet process, a large excess of water is used. In a process used by the Siempelkamp company, excess water is first removed on a machine wire web during formation of the moldings and subsequently through drying of the boards [69]. The Knauf company in Germany carries out an interesting variant of the wet process in its production of multilayer boards by prefabricating the different layers separately. A particularly imaginative version involves forming and pressing fiberboard with uncalcined gypsum. The boards are calcined in an autoclave, and water is then added so that the desired strength can be obtained by the formation of gypsum hydrate [70].

Semidry Production Process. The semidry process is particularly suitable for the production of gypsum particle board. Only a small excess of water is used (ca. 30 %) so pourable particles can be processed. By decreasing the proportion of water, the energy balance of the gypsum particle board production is improved because less free water needs to be removed from the board by drying.

Industrially produced boards have a moisture content of 15 % after pressing. They are then dried to an equilibrium moisture level of 2 %. The bulk density of the board is ca. 1150 – 1250 kg/m^3. The pressing times for gypsum are generally shorter than those for cement. Further shortening of the setting time is possible [71].

2.3.3.3. Magnesia-Bonded Boards

Magnesia-based binders have been known as Sorel cement for more than 100 years. By calcination of magnesite or dolomite at ca. 800°C, magnesium carbonate ($MgCO_3$) is converted into magnesium oxide (MgO). The latter undergoes a highly exothermic reaction with water and magnesium chloride or sulfate to give an extremely hard material. This binder system has been used for a long time for the production of wood wool boards (trade name Heraklith). Because of the high solubility of magnesium salts, the water resistance of Sorel cement is not particularly great. However, the highly exothermic nature of the setting reaction is very advantageous. Short hardening and pressing times are thus possible at low pressing temperature (100 °C). For the production of magnesia-bonded particle board, ca. 70 % binder and water and ca. 30 % wood chips are used. The binder consists of 5 mol MgO, 1 mol $MgSO_4 \cdot 7\,H_2O$, and 15 mol water. Normally, the water is applied to the wood chips; magnesium sulfate is added as a concentrated aqueous solution; and then magnesia is mixed in as a powder. At 100 – 150 °C the pressing time is ca. 10 min. The 18-mm-thick boards have a density of 1050 – 1150 kg/m^3, a transverse tensile strength of 0.65 N/mm^2, and a flexural strength of 13 N/mm^2. The thickness swelling of the boards on storage in water is < 2 %. The economic importance of magnesia-bonded board is currently low.

2.4. Surface Treatment

Wood-based panels are used mainly for interior furnishing and furniture production. Thus the appearance and decorative function of these materials are particularly important. Solid wood – both natural wood and veneers – has a very high aesthetic value. Surface treatment is aimed at increasing the decorative value as much as possible and improving properties of application.

Many techniques are known for producing certain effects in the surface treatment of solid wood or veneers. The nature of the surface can be altered mechanically by planing, grinding, polishing, or sanding, and chemically by bleaching, staining, and varnishing. Wood components in the surface are treated with bleaching or staining agents so that the natural color disappears completely or is rendered much more intense.

Materials based on glued wood particles are generally surface treated. Most are veneered, varnished, laquered, or coated with films, sheets,

or laminates. The most important requirement for surface coating is that the surface of the material to be coated should be solid and smooth.

2.4.1. Veneers

The oldest process used for the finishing of wood-based construction materials is the application of veneers.

Today, peeled veneers, in particular, are used mainly for decorating furniture and panels. Chemical stains are often used to enhance natural effects and strengthen color contrasts.

The production of veneers and their processing to give decorative surfaces is described in Section 2.2.2.

2.4.2. Liquid Paints and Coatings

Coating is the most well known type of surface finishing. The coating technique used is determined by the nature of the surface. For glued particle materials such as particle board, MDF, hardboard, wafers, or OSB, which can have very absorbent surfaces, a thick coating is necessary. Besides absorbency, the surface structure of the wood-based construction materials must be taken into account. Here, MDF has advantages over boards made of coarser particles, such as particle board and OSB.

Technological parameters of the carrier board, such as the density of the outer layers, density profile, adhesive content, water absorption of the outer layers, surface hardness, face strength, surface macrostructure, porosity, and sanding quality, have a significant effect on the ease of varnishing. Tests on particle board show that for three-layer boards the outer layer should be made of fine particles so that the surface is as closed and smooth as possible [72]. The quantity of binder in the surface layers should be at least 12 %. The density of the surface layers should be 950 g/cm^3 (max.) and the face strength not less than 1 N/mm^2 [73].

In the industrial coating of wood-based construction materials, attempts are made to compensate for unavoidable deficiencies in the surface quality of the boards by pretreatment with primers or priming films (see Section 2.4.3.1).

On modern coating production lines, finely sanded particle board is cleaned and primed, and a colored undercoat is applied, followed by the actual coating paint. Transparent or pigmented priming or coating systems that can be cured by air or radiation are used. These include:

1) Photochemically curing coating systems (e.g., UV-curing systems),
2) Microwave or electron-beam curing systems, in particular for highly pigmented coatings
3) High-solid coatings with a solid material content of > 80 %
4) Application of prepregs based on unsaturated polyesters
5) Waterborne paints based on water-soluble or dispersed polymer systems

2.4.3. Coating with Sheets, Short-Cycle Films, and Decorative Laminates

Coating with foils, short-cycle films, and decorative laminates is extremely important in industrial finishing. In Western Europe, which has the highest wood-based construction material production worldwide, more than 40 % of the surfaces were coated with these materials in 1992 [74].

2.4.3.1. Coating with Foils

Foils are thin, preformed surfaces that are glued to a wood-based panel carrier. The following types of overlaying exist:

Thermoplastic Foils. The basic material consists of poly(vinyl chloride), polyolefins, or polyester resins, which can be mass dyed, subjected to decorative printing, and embossed on the surface.

Priming foils consist of paper carrier web, which is impregnated by submersion in an aqueous amino resin solution and dried without touching in a suspension type dryer to a residual moisture level of 3 – 7 %; 60 – 120 g/m^2 paper is used. The resin content of the paper is relatively low – 60 % based on the weight of the paper.

Highly penetrating UF resins in aqueous solution are used for impregnation. These undergo extensive acid-catalyzed condensation during the drying process. Priming foils serve as a basic material for further surface treatment (e.g., printing or coating).

Decorative Coating with Foils. Decorative sheeting – an economically important surface material – also consists of paper that is impregnated with a mixture of amino resin and polyacrylate dispersions. For the production of thin sheeting, ca. 40 g/m^2 paper is used, and for thick sheeting, 80 – 120 g/m^2. The papers are usually printed before impregnation. After the paper web has been dried in a lay-on-air dryer, the surface is varnished by using doctor blades. The varnish layer of 10 – 20 g/m^2 is hardened immediately in a drying area. The sheeting is dispatched for further processing in the form of rolls.

The impregnating and drying processes place high demands on the wet tenacity of the paper. The absorption of water by the paper, its longitudinal swelling, and subsequent shrinkage in the drying tunnel are compensated for by electronic control of the web. Figure 36 shows a impregnating machine with an integrated varnish applicator (doctor blade) developed by the Vilts company in Germany.

The temperatures (100 – 180 °C) in individual drying areas can be controlled separately. The quantity of resin (UF resin – acrylate dispersion) applied to the paper is 40 – 70 % of the weight of the base paper. On applying the wood-graining decorative print, silicone-based wetting inhibitors can be added so that defects obtained during subsequent varnishing look like wood pores.

Edge Coating. In the furniture industry, edge coatings are required that fit in with the decorative surface sheeting. For edge sheeting, paper with a weight of 180 g/m^2 or more is used. The material itself is more rigid than that used for coating smooth surfaces, so that nonuniformity in the edges to be coated can be compensated for more easily. Paper-based edge sheeting is produced in various qualities. For less demanding applications, the printed paper is impregnated with an aqueous mixture of UF resin and polyacrylate dispersion. If greater resistance is required, etherified MF resins must be used. On impregnation, the paper absorbs 25 – 60 % of its weight of resin.

The resin is cured by using acid catalysts in drying tunnels heated with hot air. Paper-based edge sheeting is generally coated with varnish.

Application of this thermoset edge sheeting to a carrier board is often carried out with simultaneous forming of the edge material (soft forming). Edges with a purely thermoplastic basis, such as poly(vinyl chloride), polyolefin, or polyurethane, are also produced for these applications.

Sheeting and edge strips are fixed to the wood-based construction material with aqueous amino resins, poly(vinyl acetate) adhesives, melt adhesives, or solvent-containing adhesives. Melamine – formaldehyde resins and melt adhesives are frequently applied to the underside of the sheeting as a dry adhesive layer during sheet production. The sheeting can then be laminated onto the carrier board through the action of pressure and temperature in the press.

2.4.3.2. Decorative Films (Short-Cycle Films)

The application of quick-drying decorative films based on melamine – formaldehyde resins is the economically most important process for coating fiber- and particle board. In Europe in 1993, more than 1.3×10^9 m^2 of wood-based construction material surface was formed by this process.

An important feature of this coating process is the use of low pressure (1.2 – 2.5 N/mm^2) at 140 – 230 °C and shorter pressing time (9 – 40 s). This allows direct coating of pressure-sensitive materials.

The high pressure and long pressing time necessary for conventional processing of resin-impregnated papers for laminate production (see Section 2.4.3.3) would lead to undesirable deformation and damage to the structure of the carrier in coating particle board.

The development of melamine – formaldehyde resins that have a sufficient melt flow at low pressure and can thus form a surface was an important prerequisite for the direct press coating of particle board. The company Th. Goldschmidt succeeded in modifying melamine – formaldehyde resins by incorporating elasticizing agents so that crack-free surfaces could be produced [75].

In principle, polyester resins or prepolymers based on diallyl phthalate are also suitable. These resins allow application of lower pressure (e.g., 1.0 N/mm^2). However, for impregnating, they must be used in solvents such as acetone or methyl ethyl ketone. Also, the surface resistance

Figure 36. Schematic of an impregnating machine with contact-free drying and integrated coating applicator (Vilts, Germany) a) Paper roll exchange; b) Impregnating station; c) Drying tunnels; d) Applicator; e) Coating station; f) Sheet cooling; g) Sheet rolling and exchange

and hardness of the much cheaper melamine–formaldehyde resins are not achieved when diallyl phthalate and polyester resins are used.

Highly filled papers – either of one color or with decorative printing – with a weight of 60–130 g/m^2 are used mainly for impregnation. To form a closed surface, 100–140 wt % solid melamine resin, based on the weight of paper, is required.

More strongly elasticized MF resins are now generally used for impregnating. In these resins the molar ratio of melamine to formaldehyde is 1:1.5–2. Polyols, *p*-toluenesulfonamide, caprolactam, or sugar, for example, is used as the elasticizing component. Small quantities of wetting agents, mold release agents, and catalysts are also added to the impregnating liquor. The aqueous liquor has a solids content of 48–55 %. The impregnation of paper is usually carried out in two stages to obtain a more uniform application of resin. This is achieved by predrying after the first stage. Applying the necessary quantity of resin to the paper from a 55 % liquor in a single step is difficult.

Two-stage impregnation also offers the possibility of replacing the relatively expensive MF resin partially or completely in the first stage by a more economical UF resin. After the first impregnation step, the papers are dried to a residual moisture level of 10–15 %. They are then coated once more on both sides with an MF-resin-based liquor using doctor blades or gravure rollers. Subsequent drying in a suspended dryer to a residual moisture level of 5.5–7 % gives films that are supplied for coating particle board in the form of rolls or stacked sheets. During drying the paper web is led through a tunnel of drying areas on a cushion of hot air introduced from above and below by a system of jets. Figure 37 shows the schematic arrangement of the jets and the progress of the paper web through a drying tunnel. Figure 38 shows a machine for impregnating and drying decorative films by the two-stage process (lay-on-air dryer).

The amino resin absorbed by the paper undergoes further condensation during drying, but not complete cross-linking. Final curing of the resin takes place only on coating the fiber- or particle board carrier.

Particle board used for coating must satisfy particular requirements. Generally, three-layer particle board is used, which has a highly compressed, fine outer layer with high face strength. The density of such boards is 700 kg/m^3, and the face strength is at least 1.2 N/cm^2. For more highly stressed surfaces, two films are sometimes pressed at the same time, so that possible nonuniformity of the carrier material can be compensated for more effectively.

In the *Unibord process*, decorative films impregnated with melamine resin are placed on the particle mat during actual particle board production so that a coated board can be formed in a single pressing process [76]. The process did not achieve economic success because the indispensable closed-circuit cooling process in the press requires too much energy and prolongs the cycle times of the plant.

In developing new processes for the continuous production of particle board, the idea of direct coating of boards during production is expected to be reinvestigated.

2.4.3.3. Decorative Laminates

Decorative laminates are produced by pressing several layers of paper impregnated with synthetic resin in heated, hydraulic presses at high pressure. The resin melts and hardens to give a composite material in which the cellulose fibers of the paper have a reinforcing and strengthening function. The number of resin-containing paper layers determines the laminate thickness.

The central layer of a laminate is generally formed from several sheets of kraft paper impregnated with phenolic resin. This central layer is coated with an underlay, a decorative, and an

Figure 37. Schematic arrangement of the air jets and the course of paper through a drying tunnel

overlay paper; these three layers of paper are impregnated with MF resin. The use of MF resin has the advantage that any decorative coloration can be applied, because melamine – formaldehyde resins become absolutely colorless and transparent on pressing. Phenol – formaldehyde resins have a red-brown color and are thus not suitable.

High-Pressure Laminates. Production of high-pressure laminates (HPL) is a batchwise process. The pressure in the hydrualic multidaylight presses is 80 – 120 bar, and the pressing temperature is 140 – 180 °C. After pressing, the undersides of the layered sheets are sanded to facilitate subsequent gluing of these laminates to a carrier board. In the pressing process, several laminates are usually produced in one opening. Plates for modifying the structure allow a wide range of surface forms to be made.

To compensate for tension in the composite material and, in particular, to form a glossy surface, HPL is cooled under pressure to a temperature of ca. 80 °C before it is released from the mold. The pressing cycle times can be 30 min or more, depending on the thickness and number of laminates. Production of HPL is cost intensive because of the long pressing times required.

Continuous pressed laminates (CPL) are produced on double-belt continuous presses (Fig. 39) at pressures up to 50 bar with resin-impregnated papers from a roll.

Unlike the batch process, there is a continuous increase in pressure in the material after passing the entry of the continuous press. For technical reasons CPL can be produced economically only in a thickness range of 0.4 – 1.2 mm.

The covering of wood carrier boards with the prefabricated laminate is effected by gluing under pressure, as in the production of veneers. Decorative laminates are rigid, very stable composite materials. They can also be glued to wood carrier boards with low requirements as regards surface quality. Amino resins, poly(vinyl acetate), or melt adhesives are used for gluing.

Although decorative laminates are regarded as thermoset surface materials, thermoformability can be achieved by employing certain measures. Postforming laminates are obtained by elasticizing the impregnating resin used and incomplete curing (cross-linking) of the resins during high-pressure laminating. Local heating using IR radiation or contact heat permits a single permanent forming even with a small radius of curvature and angles greater than 180°.

2.4.4. Properties, Testing, and Uses

Coating wood-based construction materials aims at both the production of a decorative effect and the improvement of performance characteristics. The coating protects these materials from chemical and physical attack.

Properties. The following properties are important for assessment of a surface:

1) Mechanical stability: scratch resistance, impact strength, abrasion resistance, and crack resistance
2) Resistance toward physicochemical attack by water and steam (loss of gloss), food and chemicals, weathering, heat, radiation (sunlight), and fire

Test Standards. Besides standards for the assessment of painted surfaces, a number of national and international regulations exist for the classification, testing, and application of thermosets, which are widely used for coating wood-based materials. Classification/specification and determination of properties of HPL are listed in ISO 4586-1 and ISO 4586-2, respectively.

In Europe, particularly in Germany, coating of wood-based materials with short-cycle melamine films is widely used. Special standards were developed for assessment of these surfaces [77].

Uses. The surface coating of wood-based materials has been the major impetus for mass processing these materials. More than half of the fiber- and particle board produced worldwide is currently used in the mass production of furniture and building materials. Their application in wall and ceiling panels has increased considerably. Decorative laminates have revolutionized the entire kitchen furniture industry. Laminates that have been rendered highly abrasion resistant by incorporation of corundum, are being increasingly used as upper surfaces of floors. Plywood and particle board that are laminated with papers impregnated with phenol – formaldehyde resins can be repeatedly used for concrete shuttering. The use of short-cycle films in the processing of particle board moldings and profiles has also proved successful. Here, the coating and the compression molding are applied simultaneously (Werzalite process) [78].

2.5. Environmental and Toxicological Aspects

2.5.1. Wood Dust

In the production and processing of wood-based materials the formation of fine dust particles cannot be avoided. Suspicion has existed for a long time that prolonged occupational contact with wood dust increased the risk of development of adenocarcinomas in the inner nose. According to Acheson workers in the wood industry have a thousandfold greater risk of developing nose cancer than other workers; he based his theory on statistical investigations in the wood industry at High Wycombe (United Kingdom) from 1956 to 1965 [79]. No clear explanation has been found as to why wood dust should be carcinogenic. Natural wood components, materials used in working and processing wood, metabolites of wood fungi, pyrolysis products from processing, or simple mechanical irritation could be responsible for the development of adenocarcinomas [80]. Wood components particularly those of hard deciduous woods, have been suggested to be mutagenically carcinogenic [81]. Besides a large number of mutagenicity tests with wood extracts, epidemiological investigations of nose cancer in various countries, in particular, have led to the formulation of preventive measures. In many countries, adenocarcinomas of the nose have been recognized as occupational diseases of workers in the wood industry.

2.5.2. Emissions

In the production of wood-based materials, processes are used in which the main components, such as wood, adhesives, varnishes, paints, and coatings and other additives, are heated. In these processes, substances are formed or liberated that constitute emissions from the production plant. Emissions from finished materials are also sometimes detected. These are a nuisance and impair the utility of the material.

2.5.2.1. Emissions during Production of Wood-Based Materials

Dust. In large wood processing plants such as fiber- and particle board factories, considerable quantities of dust are produced in cutting and sanding processes. The dust produced from sanding machines is also polluted with adhesives and additives. Removal of dust from waste gases is mandatory. Dust separation is carried out in filters, and the dust is incinerated to produce energy.

Emission of Wood Components. Emissions are also produced during the drying of wood, which depend mainly on the intensity of the drying process. Waste gases with intense odors are liberated from wood along with water vapor. These consist of wood components such as pinenes, terpenes, phenol derivatives, aldehydes, and alcohols. The quantity of these substances can be reduced by mild drying at lower temperature, or they can be eliminated by using gas scrubbers with up to 60 % efficiency.

Adhesives. For the production of glued wood-based construction materials, several million tonnes of adhesive resins are used per year.

Formaldehyde. Condensation products based on amino and phenol – formaldehyde resins are the most important adhesives economically. On hot pressing of glued particles, fibers, or veneers, formaldehyde is emitted. In the waste gas from a 12-daylight press in a particle board factory, 13 kg of formaldehyde per hour was measured for UF adhesives and only 0.6 kg/h for PF adhesives. The quantity of formaldehyde produced in the pressing process depends on the molar ratio of urea to formaldehyde in UF resins, pressing conditions, the moisture level of the molding, and the quantity of catalyst used [82].

Formaldehyde is a very reactive gas with a pungent odor, which can be detected even in very low concentrations. The odor threshold ranges from 0.06 to 1.2 mg per cubic meter of air (0.05 – 1 ppm) and varies from one individual to another.

The hazard potential of formaldehyde to humans is due to irritation of the eyes and mucous membranes of the respiratory passages and to skin allergies (→ Formaldehyde, Chap. 10.).

After two American animal experiments in 1980 showed that inhalation of high concentrations of formaldehyde over a long period can cause nose tumors in rats, extensive research was initiated worldwide into its possible carcinogenicity. The results of these and numerous epidemiological studies are now available. In animal experiments, varying results were obtained, from which carcinogenicity in humans could not be derived. In 1994 the UNO/WHO-IRAC had no information to support the assumption of carcinogenicity. As a precaution, emission and imission values for formaldehyde and maximum workplace concentrations have been officially regulated in almost all industrialized countries.

On using PF resins, a low emission of *phenol* or (hydroxymethyl)phenols must be expected. The more strongly precondensed the PF resin is, the lower are the emissions on hot pressing.

In the processing of PMDI monomeric components (MDI) can be emitted during pressing. The high reactivity of this compound with water usually leads to immediate, nontoxic polyurea formation.

During the drying of resin-impregnated paper for coating wood-based construction materials, formaldehyde, phenols, and sometimes additives are emitted. In modern plants, waste gases from the dryers are usually purified by incineration. Scrubbing these gases would be time consuming and expensive since 15 000 – 20 000 m^3 of waste gas are produced per hour per plant. If melamine – formaldehyde resins are used for impregnation, waste gases from the dryer contain 0.3 – 0.6 g formaldehyde per kilogram of solid resin. Under the same conditions, UF resins emit up to three times this quantity. Lamination of resin-impregnated and dried papers to

Figure 41. Development of particle board and MDF production in Western Europe and the United States from 1984 to 1992

the wood-based construction material generally results in low formaldehyde emissions.

2.5.2.2. Emissions from Finished Materials

The emission of formaldehyde from wood particle board was first reported in 1962 [83]. The emissions are caused by the adhesive used, whereby formaldehyde is liberated by hydrolysis of the condensation product [44]. In the meantime, a large number of publications on this subject have appeared [84], in which the causes are determined and possibilities for lowering emissions are described [55, 85]. Many methods of measurement have been developed to adhere to the limiting values stipulated by national authorities. In Europe the perforator method (EN 120) and the gas analysis method (EN 717-2) are used as process controls to monitor emissions from particle board.

Through international cooperation, conditions for a chamber test have been worked out. In this test, the formaldehyde concentration in ambient air is measured as an equilibrium con-

Figure 42. Production of plywood, particle board, and fiberboard by the five most important producer countries in 1991

centration, and the emissions of the material are thus assessed.

In many countries, wood-based construction materials are divided into emission classes E1 – E3 according to their formaldehyde-emitting capacity. These classes represent certain ranges of values determined by the perforator method. For example, for boards in emission class E1, the consumer need not fear any emissions on proper use of the board.

No complaints of emissions from boards bonded with *phenolic resins* have been reported thus far. Values for emissions from *PMDI-bonded boards* have not yet been published.

2.5.3. Disposal

In the production of modern wood-based construction materials, considerable quantities of nonwood products are frequently used. The important materials remaining in the wood are adhesives, varnishes, paints, coating materials, dyes, wood preservatives, and flame retardants.

The waste material formed during production is mostly recycled to the process or incinerated to produce energy. Dumping is used in only a few exceptional cases, when allowed. Wood-based construction materials that are no longer utilizable and those that are at the end of their useful life are combusted. Here, their burning behavior must be taken into account, particularly in the case of nonwood substances. Incomplete combustion favors the emission of hazardous waste gas.

The emission of nitrogen oxides is determined mainly by the nitrogen content of the fuel [86]. For uncoated fiber- or particle board glued with amino resin, the nitrogen content is 3.5 – 5 %. For materials glued with phenolic resin, the

alkali incorporated with the resin inhibits propagation of burning. Wood preservatives must be incinerated under controlled conditions and the ashes disposed of separately. Chloride-containing curing aids for amino resins or coatings based on poly(vinyl chloride) give rise to the hazard of formation of polychlorinated dibenzodioxins and dibenzofurans [87]. By controlled incineration, the behavior is improved and the risk of formation of these hazardous substances is decreased.

2.6. Polymer Wood

Polymer wood consists of solid wood or wood-based materials that have been impregnated with monomers or synthetic resin solutions. The plastic components are then cured thermocatalytically or by radiation.

Plastics are incorporated in the wood texture to give a composite material with improved physical and chemical properties. The increase in strength of the wood can be seen principally in improved hardness and transverse compressive strength. The abrasion resistance of polymer wood is determined by the hardness and chemical structure of the polymer components. The dimensional stability and sorption properties are also improved, the latter being due to a significant reduction in the rate of water absorption. The effect is limited only by the fact that most monomers are deposited in the cell lumens and capillaries, but not in the cell wall itself where water is active.

In the production of polymer wood, attention is paid to the differing impregnation capacities of various types of wood and of sap- and heartwood. The liquid monomers or prepolymer solutions are applied by the vacuum-pressure process to accelerate penetration. The proportion of polymer components (30 – 60 %) determines the properties of the composite material. Direct grafting of the monomer onto the cellulose of wood is desirable [88]. Chemical catalysts, thermal energy, or radiation is used to initiate polymerization. The use of higher temperatures has the disadvantage that considerable proportions of volatile monomers are lost from the system by evaporation. Also, some wood components may inhibit polymerization and cause incomplete conversion of the monomer. The use of high-energy γ-radiation (cobalt-60) is very effective to achieve polymerization in wood [89]. In practice, a radiation dose of ca. 4×10^4 Gy (4 Mrad) is used. The surface hardness can thus be improved by up to 25 % compared with purely thermal polymerization.

The following have been proposed as monomers or prepolymer solutions:

1) Condensation resins (e.g., UF, MF, and PF resins)
2) Polyester and epoxy resins
3) Diisocyanates (e.g., MDI monomer, prepolymer, and polymer)
4) Acrylic esters, acrylonitrile, vinyl chloride, styrene, and maleic anhydride

The degree to which these substances undergo direct chemical bonding with cellulose in wood is not known for many monomers. For example, no urethane groups could be detected when diisocyanates were used, which indicated that reaction with the hydroxyl groups in wood had occurred [90]. The NCO groups can therefore be assumed to have reacted with water in the cell wall to form polyurea.

On impregnating oak with UF resin, a resin absorption of 43 kg/m^3 is achieved, and with sapwood-rich pine, 90 kg/m^3. Water absorption decreased and the compressive strength of the impregnated wood increases with increasing absorption of resin. On prolonged storage in water, the absorption of water increases again probably due to leaching of components of the impregnating agent [91].

Some of the monomers proposed present problems in industrial utilization for toxicological reasons because both the handling of these substances and their quantitative conversion in wood are difficult. A large number of processes for polymer wood production have been worked out and patented [92].

Nevertheless, polymer wood has not yet been widely used industrially. Economic reasons are mainly responsible for the reluctant utilization of this material. Polymer wood production is expensive, and its subsequent working with tools is difficult. Its resistance to weathering is not particularly high. Polymer wood is used for floors (parquet) and also for sports apparatus, tool parts, rifle shafts, and highly stressed industrial hardware.

2.7. Economic Aspects

The worldwide economic development of the wood processing industry was very positive during the decade from 1981 to 1991. The main areas of use for wood-based boards are the furniture and building industries. From 1981 to 1991, worldwide production of wood-based boards increased from 100 to 122×10^6 m^3 or by ca. 22 % [74, 93]. All types of board have contributed to this growth. The highest growth rate, 33.8 %, has been in *fiberboard* production (MDF and hardboard). The production of *particle board* has increased by 27 % to 49.5×10^6 m^3, whereas that of plywood and veneer plywood has achieved a growth rate of 18 %, and light fiberboard (*softboard*) a growth rate of 6.5 %.

Worldwide production and consumption figures for wood products are given in Table 12.

Table 12. Production and consumption of wood products worldwide (in 1000 m^3)

Product	Year	
	1981	1991
Cordwood	2 926 027	3 429 426
Wood-based panels	100 363	122 425
Particle board	39 020	49 459
Plywood	40 329	47 636
Fiberboards (including softboard)	16 517	20 201

The worldwide distribution of the production of wood-based construction materials gives an indication of the economic development of a region and the availability of corresponding raw material resources (Fig. 40).

If the three largest classes of wood-based construction materials – particle board, plywood, and fiberboard – are compared, since the 1960s particle board production has overtaken that of plywood, which was previously the leader in terms of quantity. A similar development is likely to occur with fiberboard (MDF). This can be seen, in particular, from a comparison between MDF production in Western Europe and in the United States from 1984 to 1992 (Fig. 41). In Figure 42 the quantities of particle board, plywood, and fiberboard produced by the five most important producer countries are compared.

Production of glued particle wood-based construction materials has increased markedly. The lack of round timber with large dimensions favors the use of lower-quality wood, mainly for fiber- and particle board. Improvement of the quality of glued particle wood-based construction materials, particularly in industrial processing, has also contributed to their reputation and use.

1. Introduction

Wood consumption has increased worldwide, accelerated by overfelling and fire clearing. Wood is a renewable raw material, but reforestation measures are not sufficient to compensate for the decrease in forest stands. Therefore, for economic reasons, for the protection of forests, and to lower the consumption of tropical wood, the utility of wood must be prolonged by suitable measures. Wood can undergo physical, thermal, and chemical changes, and can be attacked and even destroyed by fungi, insects, and marine animals. Wood with a moisture level of $<18–20\,\%$ is not attacked by fungi, but can be attacked by insects—in certain climates, often predom-

10.1002/14356007.a28_357.pub2

inantly by termites. If constructive wood preservation measures are not possible, or durable and weather-resistant types of wood are not available, chemical preservatives must be used. Depending on the hazard posed, different preservatives are used; these can include flame retardants. Wood preservatives are increasingly subject to registration and approval, particular attention being paid to toxicology and environmental aspects, as well as effectiveness [1]. In many respects, the requirement profiles are comparable to those of plant protection agents. In addition to biological damage, wood can also be exposed to nonbiological damage. These sources of damage and possible preservation measures are listed in Tables 1 2 3.

Table 1. Abiotic damage to wood, according to [2]

Source of damage	Type of damage	Possible protection
Mechanical	deformation, destruction	use of stronger types of wood; combined use with other materials; polymer wood
Thermal (100 °C)	discoloration, decomposition, combustion	fire-retardants; agents producing insulating layers
Chemical (acids, bases)	discoloration, destruction	suitable types of wood; surface treatment
Weathering (UV radiation, water, air)	graying, weathering, swelling, shrinkage, crack formation	resistant types of wood; surface treatment with pigmented, water-repellent paints

2. Wood Preservatives

Wood preservatives must fulfill very different requirements. Depending on the intended use, a limited period of activity (e.g., for the temporary protection of freshly felled or sawn wood) or a prolonged period of activity (e.g., for railway ties, cooling tower wood, poles, and masts) may be expected. Wood preservatives should be chemically stable, should readily penetrate into the wood, and should be resistant to leaching out, evaporation, and light. The environmental pollution during use and processing of preserved wood should be minimal. The disposal of treated wood should not lead to contamination of soil, water, or air. Other important criteria for the choice of a preservative are its corrosion properties and its compatibility with paints and coatings, adhesives, and inorganic or organic building materials. No preservatives have yet been developed that fulfill all of these demands. Considerable advances have been made in the area of water-soluble and solvent-containing preservatives (Section 2.3).

Table 2. Animal pests, according to [3, 4]

Organism causing damage	Damage location
Fresh wood insects	freshly felled logs, freshly sawn timber
Bark beetle (Scolytidae; e.g., *Xyloterus* sp.)	forests, tropics
Heartwood beetle (Platypodidae; e.g., *Platypus* sp.)	logs and sawn timber, tropics
Wood wasps (Siricidae; e.g., *Sirex* sp., *Paururus)*	logs and construction wood, forests
Dry wood insects	
House longhorn beetle (*Hylotrupes bajulus* L.)	pine sapwood (predominantly roof timbering)
Gnawing beetle (Anobiidae; e.g., *Anobium, Ptilinus)*	soft and hardwood (construction wood, furniture, works of art)
Powder post beetles (Lyctidae; e.g., *Lyctus, Minthea)*	starch- and protein-rich hardwood (tropical sawn timber, parquet, furniture, wall paneling)
Boring beetle (Bostrychidae; e.g., *Bostrychus, Heterobostrychus*)	starch-rich hardwood, fresh or dry
Termites (e.g., *Reticulitermes santonenesis* (Feytand)	soft- and hardwood in tropical and subtropical regions
Marine-wood borers	
Shipworm (e.g., *Teredo navalis* L.)	underwater wood (harbor installations, ships' hulls)
Boring isopods (e.g., *Limnoria lignorum* R.)	minimum salt content in water >0.7 %, damage increases with temperature

Wood preservatives can be divided into (1) creosote and creosote–coal-containing preparations; (2) water-soluble inorganic salt preservatives and other water-soluble, predominantly organic compounds; and (3) solvent-based preservatives (solvent-containing preparations); and (4) organic active substances for wood preservatives. The last group consists of fungicides and insecticides which can be usually formulated into modern water- and solvent-based metal-free wood preservatives.

2.1. Creosotes and Tar-Oil-Containing Products

Creosotes in particular coal-tar distillates with *bp* between 200 and 400 °C belong to the most important wood preservatives with a broad spectrum of activity. These tar oil fractions are also

Table 3. Plant pests, according to [5]

Organism causing damage	Damage location	Type of damage	Possible protection
Bacteria	wood with high moisture level (on storage in water, spraying)	partially increased permeability of the wood, excess absorption of preservative, damage to paint	
Soft rot fungi (Ascomycetes; e.g., *Chaetomium globosum* Kunze)	wood with high moisture level (cooling tower wood, wood in contact with soil)	dry rot, initially in a thin layer; microscopic cavity formation	copper-containing salt preservatives, special oil preservatives
Wood-discoloring fungi [e.g., *Aureobasidium pullulans* (de Bary) (Arnaud)]	wood with moisture level > 25 %, fresh roundwood and sawn timber, surfaces exposed to weathering	blue to black discoloration	fungicidal salt preservatives; emulsion concentrates; antifungal primers or varnishes
Brown rot [particularly dry rot fungus (*Serpula lacrymans* S. F. Gray), cellar fungus (*Coniophora puteana* Karst), hite pore fungus (*Androdia sinuosa* Karst), leaflets, Lenzites species]	wood with moisture >20 %	brown coloration, cube-shaped breaks due to cellulose degradation	salt preservatives and oils
White rot [e.g., (*Coriolus versicolor* Quelet)]	wood with moisture >20 %	marblelike discoloration; slightly fibrous, absorbent wood, because of degradation of lignin and cellulose	salt preservatives and oils

used as a mixture with the original coal-tar or mineral oils in some countries (e.g., the United States). For more than 150 years, creosotes have been used to protect railway ties, masts, poles, and wood for cooling towers and for marine timbers. The estimated period of effectiveness is between 20 and 50 years, depending on conditions. A large number of chemical compounds in combination are responsible for long-term biological protection. The most important aromatic hydrocarbons contained are acenaphthene, fluorene, phenanthrene, and anthracene. The toxic values for selected coal-tar oil fractions against wood-destroying fungi are listed in Table 4. Under unfavorable conditions the addition of termiticides is necessary [7]. In coastal waters, boring isopods (*Limnoria tripunctata*) can destroy wood in contact with water if insufficient preservative is used [8].

A large number of specifications and standards for coal-tar oils and their use exist. In Europe the Western European Institute for Wood Preservation (WEI) is in charge of the specification of tar oils. Fractions with a higher boiling range are used for wood in contact with soil or water because of the better long-term protection: middle distillate fractions are suitable for wood subjected to less demanding conditions. The creosote is usually applied to wood by using the pressure process, but fence, tree, and vine posts are also treated by using butt-end treatment.

Benzo[*a*]pyrene (BaP) present in coal-tar–creosote oil is potentially carcinogenic. It is regarded as the key substance from which the content of carcinogenic, mutagenic, and teratogenic polycyclic aromatic hydrocarbons (PAHs) is derived. Polycyclic PAHs that can be present in coal-tar oil are naphthalene, methylnaphthalenes, dimethylnaphthalenes, acenapthene, fluorene, methylfluorenes, phenanthrene, methylphenanthrenes, anthracene, methylanthracenes, fluoranthene, pyrene, and benzo[*a*]pyrene. For chemical formulas, see → Tar and Pitch. Impregnating oils with a significantly reduced content of BaP and other PAHs can now be produced [9].

Because of their strong odor, color, and tendency to sweat, particularly in impregnated pine wood, creosotes can be employed only for outdoor use. The combustibility of wood impregnated with creosote is not increased but actually decreased [10].

In the EU, application of creosote is regulated by the Commission Directive 2001/90/EC which

Table 4. Limiting values for selected coal-tar oil fractions against wood-destroying fungi (in kilograms per cubic meter of wood) according to [6] *

Fraction boiling range, °C	*Coniophora puteana*	*Poria vaporaria*	*Lentinus lepideus* (tar oil tolerant)
200–220	3.9–6.15	6.15–8.0	8.0–12.8
260–280	6.15–8.4	8.8–13.2	20.5–32.2
330–360	7.8–12.0	16.4–20.5	11.4–15.6
Coal-tar oil (creosote)	5.1–6.8	5.55–6.0	24.6–30.0

* The first value gives the largest quantity that still allows attack by fungi; the second, the smallest quantity that prevents attack.

prohibits the use of creosote as a wood preservative except in specified products (< 50 ppm of BaP, and < 3 wt % of water extractable phenols) applied in industrial installations or by professionals. The treated wood must be for industrial use (e. g., railroad ties, utility poles, agricultural stakes without food contact, marinas) only and cannot be used for residential, recreational and leisure facilities where skin contact is possible; also excluded are agricultural structures where food or plants for consumption are grown.

2.2. Waterborne Wood Preservatives

The minimum effective and toxic levels of wood preservatives for various pests are given in Table 5. The most important waterborne wood preservatives are those that are rendered insoluble by reaction of the components with one another in the wood and those that become tightly bonded to the wood fibers, so that they are resistant to being leached out. The first group comprises inorganic salt mixtures that are fixed in the wood by chromium(VI) compounds [alkali-metal chromates and dichromates, and chromium (VI) oxide]. Chromium is responsible for fixation. It is reduced during the fixation process to almost insoluble chromium(III). The second group consists of organic compounds that are applied to wood in the aqueous phase and become bonded to the fibers or are precipitated to form insoluble compounds in the wood. Waterborne preservatives are usually applied by the pressure process. However, tank and butt-end treatment processes can also be used. Certain fluorine and boron compounds, which are suitable wood preservatives, are not fixed and can therefore be used to protect only wood that is not exposed to moisture. Fluorine is partially fixed in the presence of chromium(VI) compounds.

2.2.1. CCA and Variations

For a long time copper–chromium–arsenic salt mixtures (CCA) were the most widely used wood preservatives due to their broad-spectrum activity, lasting permanence in the wood, and excellent cost efficiency. The salt mixtures can have varying compositions. Arsenic(V) compounds used include arsenic pentoxide, arsenic acid, and disodium arsenate. In addition to chromates, the following copper(II) compounds are used: copper sulfate, basic copper carbonate, or copper oxide. Acid fixation of CCA salts occurs in various phases. Chromium(III) arsenate, basic copper arsenate, and chromium(III) hydroxide are formed. The length of the fixing process depends on the moisture level in the wood, pH, and temperature, it can be several days to several weeks [12]. A large number of theories exist about the mechanism of CCA fixing [13].

Variations of CCA such as ammoniacal copper arsenate (ACA), ammoniacal copper–zinc arsenate (ACZA), copper–chrome–boron (CCB), and copper–chrome–fluorine (CCF) had been developed as substitutes for arsenic or chromium containing compounds in order to comply with national legislations or for specific applications. However, none of these CCA variations became universally accepted because of performance or handling disadvantages (e. g., boron and fluorine compounds can be easily leached out of wood) and because more environmentally friendly chromium- and arsenic-free compounds became available in the meantime.

Whilst still being employed in many countries the use of CCA as wood preservative has been restricted or banned in the USA, Europe (EU), and Japan because of environmental and health concerns.

Table 5. Minimum effective and toxic levels for various types of salt preservatives (in kilograms per cubic meter of wood) according to [11]

Type of preservative	Brown rot		Soft rot		Wood longhorn beetle
	Unaged	Leached	Unaged	Leached	Unaged
Boron compounds	1				0.4
Copper sulfate	25–50	> 50	4	ca. 15	1
HF	1				0.3
SiF	1.5				0.3
Cu–Cr–As	6	12	7	15	2
F–Cr–As	2.2	11	> 50	> 60	0.5
Cu–Cr–B	2.5	20	4	10	2
Cu–Cr–F	2.8	12	5	6	0.7
F–Cr	3	14	ca. 50	> 60	0.5

2.2.2. Copper-based (Chromium- and Arsenic-Free) Wood Preservatives

Waterborne copper-based products are the most important class of wood preservatives especially for the hazard classes (HC) 3 (exterior wood above-ground) and 4 (wood in-ground), even though there is a trend to replace them with metal-free (or totally organic) wood preservatives for HC 3. Most widely used products of this class are ammoniacal copper quarternary ammonium compounds (quats) (ACQ) and copper azoles (CuAz) followed by bis(*N*-cyclohexyldiazeniumdioxy)copper (Cu-HDO) (**2**), whereas ammoniacal copper dithiocarbamate (CDDC) [14, 15] and ammoniacal copper citrate (CC) [16] play only very minor roles, because their efficacy spectrum is not broad enough to compete with CuAz or ACQ.

Copper applied in a suitable form provides already on its own a broad spectrum of protection to wood, because it is effective against most wood rotting fungi including soft rot species, as well as insects including termites. However, a number of species are tolerant to copper, the copper tolerant brown rot species are the most relevant of these. Therefore, the effectiveness of copper-based wood preservatives highly depends on the choice of cofungicide which ideally should fully and efficiently cover this efficacy gap of copper [17].

ACQ contains CuO and as cobiocide the quat di-*n*-decyldimethylammonium chloride [*7173-51-5*] (DDAC), or alternatively in a newer version also benzalkonium chloride [*8001-54-5*], in a ratio of 2:1. The addition of ammonia or an amine such as ethanolamine is required for the fixation of copper by formation of the corresponding copper complex. Typical standard retentions of ACQ are 4.0 kg/m^3 for HC 3, and 6.4 kg/m^3 for HC 4 [18]. ACQ treated timber performs very well under different conditions in many situations of use, especially when a water repellent is included in the preservative [19 – 21].

Copper azoles (CuAz) exist in several versions with variations of the azole part and with or without boron as additional booster of the insecticidal efficacy. Examples are copper tebuconazole, copper boron tebuconazole, and copper boron tebuconazole/propiconazole. The azole fungicides such as tebuconazole which are emulsified in copper azoles formulations have proven to be very effective against the copper tolerant brown rot fungi. Therefore, only low concentrations of azole are required to compensate for the copper efficacy gap, i.e., an azole to copper ratio of 1:25 is sufficient. Usually copper is provided as CuO or alkaline copper carbonate and ethanolamine is applied as fixation agent. Specified standard retentions of copper azoles (e. g., copper tebuconazole 1.7 kg/m^3 for HC 3, and 3.3 kg/m^3 for HC 4) [18] lead to excellent performance in many end uses [21 – 23].

N-Cyclohexyldiazenium chelates [24, 25] have been known in Europe as wood preservatives for many years. (Cu-HDO) (**2**) is rendered water soluble by copper–amine complex formation and is a chromium-free wood preservative that can be used in the pressure process [26]. Because of its good fixing properties and effectiveness against wood-destroying basidiomycetes, this preservative is also suitable for wood in continuous contact with moisture. Addition of copper(II) hydroxide carbonate improves the activity against soft rot, and addition of boric acid, which penetrates deeply by diffusion, has proved effective in protecting heart-

wood [27]. The toxic values for Cu-HDO and is 0.8–0.9 kg [27] per cubic meter of wood towards *Coniophora puteana* after leaching out. In the incineration of Cu-HDO-impregnated wood the composition of the flue gases, (CO, CO_2, HCN, and NO_x content) corresponds almost exactly to that of untreated wood [28].

Water-soluble *N-cyclohexyldiazeniumdioxypotassium* [*185843-92-9*] (K-HDO) (**1**) is added to adhesives for the production of wood-based construction materials to hinder attack by basidiomycetes such as *Coniophora puteana* and *Gloeophyllum trabeum* [29].

1

2

2.2.3. Boron Compounds

Boric acid, borax, and other polyborates, such as disodium octaborate tetrahydrate, are themselves wood preservatives and components of wood preservatives and flame retardants, and boron compounds are also suitable for protecting wood against termites [30]. Boron compounds protect wood against brown and white rot, and against the larvae of the house longhorn beetle (*Hylotrupes bajulus*) and the common furniture beetle (*Anobium punctatum*, larvae are called woodworm) [31, 32]. Because of their water solubility and their inability to be fixed, use of these compounds is limited mainly to wood not exposed to rain. All the common processes can be used to apply these preservatives. Because of the good diffusion capacity of boron compounds in moist wood, they are particularly suited to diffusion processes [33].

2.2.4. Quaternary Ammonium Compounds

Quats were introduced in New Zealand in 1978 as wood preservatives to counteract basidiomycetes and soft rot fungi [34, 35]. Extensive investigations on this class of compound have shown that *di-n-decyldimethylammonium chloride* [*7173-51-5*] is the most effective [36 – 40]. The toxic values against basidiomycetes are 1.0–6.2 kg of active substance per cubic meter wood [41]. Di-*n*-decyldimethylammonium chloride is applied in the pressure process or by dip treatment. Like other quats used in wood preservation (e.g., benzalkonium chloride), DDAC is not suitable for wood in contact with ground. In the wood, quats are bonded more strongly to lignin than to cellulose. The tolerance of the cellulose-degrading fungus *Coniophora puteana* to quats is attributed to this [42]. When applied in quantities of 2.0–4.0 kg/m^3, DDAC is also active against soil termites [43]. Apart from DDAC, *benzalkonium chloride* [*8001-54-5*] is also employed. Its average toxic value against fungi is 4.0 kg/m^3 [44, 45]. New developments focus on quats with other anions such as propionates or carbonates to avoid the presence of the corrosive chloride ion [46, 47]. Besides the corrosive properties of the anion, DDAC or benzalkonium chloride treated wood has also the disadvantage of being incompatible with many paints and coatings.

Polymeric betaines, which contain cationic alkylammonium groups and anionic borate groups, are suitable wood preservatives for use in brushing, dipping, and vacuum pressure processes for control of wood-destroying fungi, blue stain fungi, and insects. The commercial product contains *N,N*-didecyl-*N,N*-dipolyethoxyammonium borate/didecylpolyoxethylammonium borate [*214710-34-6*] as the active substance [48]. For basidiomycetes the toxic values after leaching test procedure are 7.6 kg/m^3 (aqueous solution) and 3.5 kg/m^3 (solvent-containing formulation). To prevent the development of house longhorn larvae, the retention of 0.3 kg (aqueous formulation) or 0.17 kg per cubic meter of wood (solvent-containing formulation) is sufficient. For wood that is continually in contact with soil and moisture, a salt was developed for the pressure impregnation process that contains betaine and copper amine [49, 50].

Toxicology. Polymeric betaines are nonmutagenic and nonsensitizing. The LD_{50}, oral, rat,

is between 500 and 2000 mg/kg. Their vapor pressure is very low (not determinable), and no toxic products are formed on incineration of impregnated wood [51].

2.2.5. Phenol Derivatives

Water-soluble *sodium pentachlorophenoxide* [*131-52-2*] is still used in several countries for temporary protection of sawn timber and veneers against discoloring mold and fungi, despite toxicological concerns and the consequent limitations on its use (see Section 2.3.1). It is often used in mixtures with borax [*1303-96-4*] to improve the activity against insects. The preservative is applied either by spraying or by dipping.

2-Phenylphenol [*90-43-7*], biphenyl-2-ol, 2-hydroxybiphenyl, is suitable for treating sawn timber against discoloring fungi and mold. An aqueous alkaline phenoxide solution is applied that reacts with the acidically reacting wood surface to form 2-phenylphenol, which is almost insoluble in water. 2-Phenylphenol has a low toxicity and is approved as a preservative in many countries. The substance is readily biodegradable and environmentally acceptable [52].

2.3. Solventborne Wood Preservatives

Solventborne wood preservatives are formulations comprising nonpolar, organic solvents and at least one biocide. The largest group consists of products with volatile (light) organic solvents (LOSP). They have the advantage that a second coat can be applied to the protected wood, which is not possible for wood treated with heavy-oil-containing preparations. Depending on the purpose envisaged, solvent-borne wood preservatives frequently contain solubilizers, binders, fixing agents, agents that counteract efflorescence of the active substance, pigments, dyes, light stabilizers, and water repellents. Solventborne wood preservatives penetrate wood without altering its structure (dimensions). These preservatives can be applied by brushing, injecting, spraying, dipping, or the double vacuum process with or without pressure.

2.3.1. Pentachlorophenol

Pentachlorophenol (PCP) [*87-86-5*] was a universally accepted wood preservative for many years, because it shows a very broad spectrum of activity against fungi and insects, and is resistant to biodegradation leading to good long-term protection. Today, the use of PCP is restricted or forbidden in many countries not only because of its persistency in the environment but also because of the possible formation of highly toxic polychlorinated dibenzo-*p*-dioxins, particularly octachlorodibenzo-*p*-dioxin (OCDD), on heating PCP or incinerating PCP-treated wood, and the possible presence of dioxins as impurities in technical-grade PCP. Nevertheless, in the USA PCP is still a popular preservative for utility poles where it is applied dissolved in diesel oil by pressure treatment at retention levels of 5–8 kg per cubic meter of wood for pine species [18].

2.3.2. Tributyltin Compounds

Bis(tributyltin) oxide [*56-35-9*] TBTO and other tributyltin compounds such as *bis(tributyltin) naphthenate* [*85409-17-2*] TBTN have been known since the 1950s as effective wood preservatives, in particular against wood-destroying brown and white rot fungi and insects. However, since their insecticidal activity is limited, addition of an insecticide (e. g., permethrin) is required where appropriate. Assessment of the effectiveness against white and soft rot fungi has led to conflicting results [53 – 55]. For toxicological reasons, use of tributyltin compounds has phased out in Europe and Japan. In Australia, New Zealand TBTN is still used in the double vacuum process for impregnating window wood, frames, and wooden doors made of softwood. Differing data exist for the period of activity, ranging from 5 to 30 years [56 – 59]. Various fungi and bacteria are able to detoxify TBTO [60]. TBTN is less volatile than TBTO.

Toxicology. For TBTO the LD_{50}, oral, rat, is 127 mg/kg, and for TBTN 224 mg/kg. Toxic values for the wood-protecting activity of TBTO are between 0.5 and 1.0 kg per cubic meter of wood for *Coniophora puteana* after leaching test procedure.

2.3.3. Metal Naphthenates

Of the metal naphthenates, *copper naphthenate*, in particular, is used against wood-destroying fungi and insects in the United States, and Asia/Pacific Rim. It is also used for impregnating poles in the pressure process [61] at retention levels of up to 2.4 kg Cu per cubic meter of wood [18]. Persistence of the active substance in the wood depends largely on formulation [62, 63]. The green coloration of treated wood can be undesirable. Besides copper naphthenate, zinc naphthenate is also used against wood-destroying fungi.

2.3.4. Oxine copper

Oxine copper [*10380-28-6*], Cu-8, bis(quinolin-8-olato-*O*,*N*) copper, is a copper chelate with 8-hydroxyquinoline. It is dissolved in organic solvents for pressure impregnation of wood for greenhouses, seed containers, transport containers for foods, etc. Cu-8 is only specified for above-ground applications and certain wood species. Water-soluble oxine copper formulations produced by using dodecylbenzenesulfonic acid are employed to suppress the development of discoloring (sapstain) fungi and molds on freshly felled wood [64]. A particular feature of oxine copper is its low toxicity toward warm-blooded animals and its good compatibility with plants.

2.4. Organic Active Substances for Wood Preservatives

Copper-based wood preservatives are inevitable for the protection of wood in ground contact (HC 4) as none of the organic fungicides tested is sufficiently effective against soft rot. However, for the protection of wood above ground (HC 3) modern metal-free wood preservatives have been developed since the 1990s. These are either waterborne or solvent-based wood preservatives with acceptable toxicological and environmental profile, which require usually combinations of two or more organic active substances including an insecticide to cover the full spectrum of biological hazard wood is facing. As most of the organic active substances are either very sparingly or practically nonsoluble in water, they are emulsified in the waterborne formulations.

2.4.1. Fungicides

2.4.1.1. Triazole Derivatives

The triazole fungicides are the most potent organic fungicides used in wood preservation forming the core part of many modern formulations for the treatment of above-ground wood. Azaconazole [*60207-31-0*], 1-[(2-(2,4-dichlorophenyl)-1,3-dioxolan-2-yl)methyl]-1*H*-1,2,4-triazole [65] was the first triazole introduced to wood protection in the mid-1980s. It has been used mainly as anti-sapstain agent in combination with quats for the treatment of sawn timber. In 1989 and 1990 two other triazoles, which have already proved effective in plant protection, have been developed as actives for wood protection with pronounced activity toward wood-destroying fungi. They are propiconazole [*60207-90-1*], 1-[2-(2,4-dichlorophenyl)-4-propyl-1,3-dioxolan-2-ylmethyl]-1*H*-1,2,4-triazole [66] and tebuconazole [*107534-96-3*], α-*tert*-butyl-α-(4-chlorophenylethyl)-1*H*-1,2,4-triazole-1-ethanol [67]. These triazole fungicides are effective against wood-destroying basidiomycetes, and blue stain fungi. The toxic values after evaporative aging of tebuconazole (propiconazole) against the important brown rot test fungi *Coniophora puteana, Gloeophyllum trabeum*, and *Poria placenta* are 0.05 (0.31–0.39) kg/m^3, 0.05 (0.57–0.64) kg/m^3, and 0.15–0.31 (0.10–0.15) kg/m^3, respectively. The combination of tebuconazole and propiconazole (1:1) provides not only a more balanced efficacy spectrum against brown rot than the single components but also is synergistically effective against the white-rot fungus *Coriolus versicolor* [68]. Therefore, the combination of tebuconazole and propiconazole is widely used as anti-basidiomycetes component. In treated wood, both propiconazole and tebuconazole are highly resistant to leaching and evaporation [69]. Another promising triazole for wood protection is cyproconazole [*94361-06-5*], α-(4-chlorophenyl)-α-(1-cyclopropylethyl)-1*H*-1,2,4-triazole-1-ethanol [70], which is very effective against wood rotting basidiomycetes,

however, its water solubility and its vapor pressure are less favorable regarding long-term protection compared to tebuconazole and propiconazole. The *toxicity* of these triazole fungicides toward warm-blooded animals is low.

2.4.1.2. Polychlorinated Aromatic Compounds

Besides pentachlorophenol (Section 2.3.1), chlorothalonil [*1897-45-6*], CTL, 2,4,5,6-tetrachloro-1,3-benzenedicarbonitrile, is used in wood preservatives mainly as cofungicide for the treatment of freshly sawn timber. In the search for alternatives to CCA, CTL was tested for its effects on wood-destroying basidiomycetes and soft rot because of its range of activity, low environmental impact, and low toxicity to mammals [71]. Stakes soaked in oil-borne formulations were almost unaffected by basidiomycetes over a period of several years; the application rate was in the range 6–12 kg CTL/m^3 of pine or eucalyptus wood [72, 73]. Further investigations confirm its potential at these high retention levels although its nonfavorable penetration profile as well as the high depletion rates have to be considered [74, 75].

2.4.1.3. Isothiazolones

Of the *N*-substituted isothiazolones, 4,5-dichloro-2-*n*-octyl-4-isothiazoline-3-one [*64359-81-5*], DCOIT, in particular has been tested for its effect on wood-destroying fungi and soft rot under severe conditions such as the soil burial test and the L-joint test [76 – 78]. Although DCOIT exhibited good performance in these trials, it is not commonly used in wood preservatives.

Toxicology. The LD_{50}, oral, rat, for a formulation containing 25 % a.i. (RH 287) is 1.56 g/kg.

2.4.1.4. Phenylsulfamides

The phenylsulfamides dichlofluanid [*1085-98-9*], *N*-dichlorofluoromethylthio-*N′*,*N′*-dimethyl-*N*-phenylsulfamide, tolylfluanid [*731-27-1*], and *N*-dichlorofluoromethylthio-*N′*,*N′*-dimethyl-*N*-tolylsulfamide [79, 80] are added to solvent-based wood preservatives in quantities of 0.4 to 0.8 % to protect wood against blue stain fungi and mold. The depth of penetration of the active substance into wood depends on the formulation. Both compounds are only stable in acidic aqueous formulations [81], thus, they are not suitable for the majority of the waterborne wood preservatives. Particular properties of these substances are light stability, resistance to leaching out, and involatility.

Toxicology. For both substances the LD_{50}, oral, rat, is 5000 mg/kg.

2.4.1.5. Iodine-Containing Compounds

3-Iodo-3-propynyl butyl carbamate [*55406-53-6*] IPBC, in principle is active against both wood-destroying and discoloring fungi [82], however, it cannot be used for long-term protection due to its easy biodegradability and relatively high leachability [83, 84]. Thus, it is mainly used as anti-mold and anti-blue stain additive in wood preservatives for HC 3 or as antisapstain agent in combination with quats or other fungicides [85, 86]. The good penetrating capacity of the substance is important when it is used in solvent-borne formulations to avoid damage by blue stain fungi [80].

Toxicology. The acute toxicity toward warm-blooded animals is low. The LD_{50}, oral, rat, is 1580 mg/kg.

2.4.1.6. Thiocyanates

2-(Thiocyanomethylthio)benzothiazole [*21564-17-0*], TCMTB, is used mainly for control of discoloring fungi in freshly sawn timber. The period of activity is three to five months [87 – 89]. The effectiveness of TCMTB can be improved significantly by combination with *methylenebis(thiocyanate)* [*6317-18-6*], MBT, which is also effective against discoloring fungi and molds. MBT penetrates rapidly in wood and exhibits high initial activity, while immobile TCMTB remains active on the surface [90, 91]. TCMTB also attacks soft rot [92] and brown and white rot. The toxic values against brown

rot fungi vary [93]. TCMTB is also used to protect wood-based construction materials against fungi.

2.4.2. Insecticides

For toxicological and ecotoxicological reasons, particularly their persistence in the environment, the use of chlorinated hydrocarbons, such as aldrin [*309-00-2*], dieldrin [*60-57-1*], chlordane [*12789-03-6*], and heptachlor [*76-44-8*], has been prohibited in many countries [94].

2.4.2.1. Synthetic pyrethroids

The pyrethroids are the most widely used class of insecticides in wood preservation because of their broad-spectrum activity, high efficacy especially against wood boring beetle, and high resistance to leaching [95]. Most popular are permethrin [*52645-53-1*], 3-phenoxybenzyl (1*RS*,3*RS*; 1*RS*,3*SR*)-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylate; cypermethrin [*52315-07-8*], (*RS*)-cyano-3-phenoxybenzyl-(1*RS*,3*RS*; 1*RS*,3*RS*)-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylate; followed by bifenthrin [*82657-04-3*]; 2-methylbiphenyl-3-ylmethyl-(*Z*)-(1*RS*)-*cis*-3-(2-chloro-3,3,3-trifluoroprop-1-enyl)-2,2-dimethylcyclopropanecarboxylate deltamethrin [*52918-63-5*], (*S*)-α-cyano-3-phenoxybenzyl-(1*R*,3*R*)-3-(2,2-dibromovinyl)-2,2-dimethylcyclopropanecarboxylate; and cyflutrin [*68359-37-5*], (*RS*;*SR*)-α-cyano-4-fluoro-3-phenoxybenzyl-(1*RS*,3*RS*; 1*RS*,*SR*)-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylate which may be used against insects attacking dry wood, in particular house longhorn larvae. Synthetic pyrethroids, take effect through direct contact, inhalation, and feeding. They also repel termites [96]. The protective effectiveness against the common furniture beetle is achieved at low retentions as follows: permethrin 50–80 g/m^3, cypermethrin 20–30 g/m^3, cyfluthrin 8–12 g/m^3, and deltamethrin 1–2 g/m^3 [97]. For the protection against termites two to three times higher retentions are required. The efficacy of the pyrethroids towards insects correlates qualitatively with the acute toxicity which ranges from 1500 mg/kg (LD50, oral, rat) for permethrin to 53 mg/kg (LD50, oral, rat) for bifenthrin [98].

2.4.2.2. Neonicotinoids

Imidacloprid [*138261-41-3*], 1-(6-chloro-3-pyridylmethyl)-*N*-nitroimidazolidin-2-ylideneamine, selectively acts on the insect nervous system as an agonist of the nicotinic acetylcholine receptor resulting in broad-spectrum activity against insects [99]. In contrast to the pyrethroids it is especially effective towards termites. In field trials, imidacloprid has shown to be protective against termites at retentions even lower than 3 g per cubic meter of wood [100]. It is also an effective termiticide for veneer-based products such as plywood [101]. Another neonicotinoid that promises high potential for wood protection is thiacloprid [102].

2.4.2.3. Insect Growth Regulators (IGR)

Insect growth regulators act highly specific on the endocrine and hormone systems of insects inhibiting the further development of the larvae and the eggs, respectively. Fenoxycarb [*72490-01-8*], ethyl [2-(4-phenoxyphenoxy)ethyl]carbamate [103, 104], and flufenoxuron [*101463-69-8*], 1-[4-(2-chloro-α,α, -trifluoro-*p*-tolyloxy)-2-fluorophenyl]-3-(2,6-difluorobenzoyl)urea [105] demonstrate good preventive effectiveness against wood boring beetles, having a favorable toxicological profile at the same time. However, they are not able to protect wood against termite attack due to their mode of action.

2.4.2.4. Phosphate Esters

The phosphate esters belong to an older generation of insecticides which are decreasingly used in wood protection due to both toxicological issues (prohibited in Japan) and the availability of more efficient compounds. Among the phosphate esters, phoxim [*14816-18-3*], *O*,*O*-diethyl-α-cyanobenzylideneaminooxyphosphonothioate, which is effective against the house longhorn and other beetles [79], and chlorpyrifos [*2921-88-2*] [106], *O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridyl) phospho-

nothioate, which are used for controlling termites, should be mentioned in particular. However, the period of activity is limited under hot, dry conditions [107 – 110].

2.5. Wood Preservatives for Special Applications

Because of their high toxicity, use of the fumigants hydrogen cyanide or methyl bromide for insect control has greatly receded and is limited to special areas such as art works. They may be used only by trained specialists. The use of methyl bromide is expected to be limited because of possible damage to the ozone layer [111]. Sulfuryl fluoride is replacing it successfully [112].

For combating wood-destroying fungi inside wooden poles (made, for example, from Douglas pine), which have only a small proportion of impregnatable sapwood, trichloromethane; chloropicrin [*76-06-2*]; vapam [*137-42-8*], sodium *N*-methyldithiocarbamate; methyl isothiocyanate [*556-61-6*], MIT; and dazomet [*533-74-4*], 3,5-dimethyltetrahydro-1,3,5(2*H*)-thiadiazine-2-thione are suitable. Their fungicidal activity is effected via the gas phase. These substances are also used in agriculture as soil disinfectants. In wood, they are injected in various formulations into diagonally bored holes, which are then closed. Depending on the type of wood, its moisture level, and the diffusion capacity (distant effect), satisfactory effective activity has been established years after application [113 – 117], for chloropicrin up to nine years [118]. However, vapam is the most frequently used fumigant.

2.6. Flame Retardants

Flame retardants are intended to lower the flammability and combustibility of wood and thus reduce the hazard of destroying it by fire. They may be classified into three types according to their mode of action [119]: charring-promoting, barrier-layer-forming, and insulating-layer-forming flame retardants. All flame retardants are suitable only for interior use.

Charring-promoting flame retardants. consist mainly of impregnating inorganic salts, such as those based on ammonium phosphates, alkali-metal borates, and hydrogencarbonates and sulfates. Wood impregnated with these substances forms noncombustible and heat-insulating charcoal layers when attacked by fire, thermal degradation of the wood substance is thus slowed down. Of the salts that, on heating, form gases that smother the flames, ammonium phosphate is particularly important.

Barrier-Layer-Forming Substances. Substances based on water glass or borates form a thin barrier layer on the wood surface, which is not readily flammable and hinders the entry of oxygen. These substances are applied by brushing. Potassium water glass, with additives such as gypsum, kieselguhr, chalk, barytes, or zinc oxide, reacts with atmospheric carbon dioxide to form hygroscopic potash and a brittle silicic acid layer.

Solid-Phase Char-Forming Substances. The mode of action of these flame retardants is based on the fact that the insulating charcoal layer is not formed in or from the wood but on its surface. Substances are used that swell on heating to form foams, and that char and solidify at flame temperatures of 250–300 °C. Such foam-forming mixtures consist, for example, of phosphates, borax, paraformaldehyde, formaldehyde, and compounds with a high nitrogen content such as urea, guanylurea phosphate, guanidine, and dicyandiamide. Paints and coatings that form insulating layers contain either special plastics that swell on heating, swelling graphite, or mixtures of binders and foam-forming fillers.

3. Uses of Wood Preservatives

Forestry. Particularly in tropical and subtropical regions, susceptible types of wood—after felling and debarking of the logs—must be protected against fungi (mainly discoloring fungi) or insects that attack fresh wood. On prolonged storage or transport, repeated treatment can be necessary. Emulsion concentrates, which can be diluted with water, solvent-borne preparations, or waterborne salt preservative solutions, can be used.

Sawmills. If wood cannot be dried immediately after sawing, it must be protected primarily against discoloring fungi (blue stain fungi) and mold, depending on its susceptibility. The most effective method is short-term dipping. In addition, the spraying process is often used. The same preservatives are used as for the protection of roundwood. After peeling, veneers are sprayed only with preservative. Sawn timber may have to be treated a second time before transportation, for example, by sea, and piles of wood may have to be covered with sheeting for protection. For tropical woods, such as abachi, limba, ilomba, and wenge, that are prone to attack by insects precautionary treatment against attack by lyctus and wood-boring beetles and other insects is necessary.

Structural Engineering. Building lumber, wooden building components, and wood-based construction materials can be attacked and destroyed by fungi and insects, and also by termites in tropical and subtropical regions, depending on the type of wood and the environmental conditions. The wood preservation measures needed depend on the stress and the endangerment of the wood, for example, through continuous contact with soil, continuous or frequent wetting by rain, or use indoors in wet areas. Water-soluble salt preservatives are most common. These are applied to the wood by vacuum, pressure, tank, impregnation, dipping, brushing, injection, spraying tunnel, or flow coating processes. In addition, solvent-containing, low-solvent, and solvent-free formulations are used to protect nonload-bearing building components, such as outer doors and windows. In countries such as Japan, the United States, and Canada, where wood is used widely in building, flame retardants are important, either in the form of water-soluble salts or flame retardant paints or as coatings that form an insulating layer. Particular demands are made on wood preservatives and impregnating processes if, for example, highly stressed poles, railway ties, mine props, marine timber, cooling tower timbering, and posts need to be protected. Apart from a broad spectrum of activity, good penetration capacity and high resistance to leaching are required.

Wood-based materials include particle board, plywood, veneers, laminated board, and fiberboard (→ Wood). Depending on use, protection against wood-destroying fungi and soft rot fungi is necessary and, in some countries, against insects as well. Within the framework of quarantine regulations regarding packaging woods, including plywood boards, the Australian authorities also require precautionary measures against insects (lyctus and termites) [120]. Special concentrates of fungicides, insecticides, or water-soluble salt preservatives are used. These are added to the adhesive liquor or to the particles in the mixer during particle board production. To reduce possible flame propagation, flame-retardant layers or coatings forming insulating layers can be applied.

4. Methods for Testing Wood Preservatives

Wood, characterized by a large number of species of different composition and properties, can be attacked and destroyed by harmful organisms. The hazard depends on the wood's natural durability under the conditions in which it is used. Because of this, methods for testing the efficiency of wood preservatives are particularly important. They should be rapid, reliable, reproducible, and based on practical situations. They must give an indication of the effectiveness of preservation and its duration under changing conditions of use. Preservatives can be tested on wood in contact with nonsterile soil substrates, in the field, or with marine organisms. Another possibility is to use efficient breeds of important wood-destroying insects (e.g., *Hylotrupes bajulus* [121, 122], *Anobium punctatum* [123], and *Lyctus brunneus* [124]), termites [125], and—for testing with fungi—pure cultures of wood-destroying basidiomycetes, soft rot fungi, blue stain fungi, sapstain fungi and molds.

Many institutions in Europe, the United States, Canada, Australia, Japan, and other countries have developed standard test procedures for wood preservatives. These include not only biological tests, but also those concerning the treatment of wood with preservatives, specifications for wood preservatives, analytical procedures, corrosion tests, and tests for flame retardants. As far as possible, the tests should be carried out by using international standard procedures to avoid, for example, lengthy and expensive repetition of tests in the approval of new active substances.

The European standard for wood preservation is particularly important here [126]. It should guarantee uniform assessment of wood preservatives throughout Europe [127 – 129].

In testing not only are organisms relevant to the envisaged area of use incorporated, but test objects treated with wood preservatives are pretreated before the biological tests to simulate later conditions of use. These measures for accelerating the aging of treated wood before biological tests include leaching, evaporation (wind tunnel test), and weathering. Test procedures that are carried out under conditions of use, frequently over a period of several years, are also important. In these tests, proven wood preservatives are used as standards [130].

In Europe, Japan, and the United States, a variety of test procedures have been specified for testing flame retardants for wood and wood-based construction materials [130 – 136].

Internationally, research activities in wood preservation are coordinated by the International Research Group on Wood Preservation (IRG; IRG Secretariat, S-100 44 Stockholm, Sweden). Five working groups are involved with the following aspects of wood preservation:

Section 1 :	Biology
Section 2:	Test Methodology and Assessment
Section 3:	Wood Protection Chemicals
Section 4:	Processes and Properties
Section 5:	Environmental Aspects

5. Approval of Wood Preservatives

European Union. Within the EU, wood preservatives are from 2009 onwards to be registered under the Biocidal Products Directive (BPD; Directive 98/8/EC), which regulates the authorization and placing on the market of biocidal products and active substances used therein. The aim of the BPD is to provide a high level of protection for humans, animals, and the environment, to harmonize the common market for biocides, and to establish a positive list of active substances (Annex I to the BPD) which may be used in biocidal products, e. g., wood preservatives (Product Type 8). The BPD distinguishes between new active substances, which were not used in biocidal products prior to May 14, 2000, and existing active substances, which were used before this deadline and are subject to a review program. The full dossier for existing active substances used in wood preservatives with exhaustive data requirements (especially on toxicological and ecotoxicological properties) had to be submitted by March 2004. The risk-based evaluation and decision on active substances was supposed to take about two years, however, is still ongoing at the time of writing of this article. Once all active substances of a given wood preservative will have been included in Annex I, it will have to be authorized at Member State level. If Annex I entry of a substance is refused, a phase-out period will be defined at that time. Wood preservatives containing active substances, which have not been supported by a full dossier, had to be taken from the market by September 2006. New active substances have to be approved before being placed on the market for biocidal uses. Until the respective active substances will have been listed in Annex I, existing national regulations for wood preservatives will remain in place.

United States. The EPA is responsible for registration of new wood preservatives. A complete and detailed documentation of the chemical, toxicological, and environmental properties of the individual components and the final formulation is required. The EPA is in charge of the Office of Special Pesticides Review (OSPR), which tests wood preservatives already on the market. When a product or component may possibly be carcinogenic, mutagenic, teratogenic, or too toxic to humans and animals, a Rebuttable Presumption Against Reregistration (RPAR) is ordered. Finally, OSHA stipulates health and safety standards for industry (e.g., maximum workplace concentrations of wood preservatives) [118].

Germany. Because of building regulations in Germany, wood preservatives used for load-bearing and reinforcing building components must have a test certificate issued by the German Institute for Construction Engineering (Deutsches Institut für Bautechnik, DIBT). A committee, consisting of wood preservatives experts and representatives of the DIBT, the UBA, and the Federal Institute for Risk Assessment (Bundesinstitut für Risikobewertung, BfR), assesses the biological effectiveness of the preser-

vative, and its effects on health and the environment, on the basis of documents submitted.

6. Analysis

Qualitative and quantitative analysis procedures have been developed, and in many cases standardized, to determine the distribution and presence of preservatives or preservative components in treated wood or wood-based materials. Depending on the treatment process, type of wood, and proportions of sap- and heartwood, the distribution of preservatives in wood can vary widely. Since treated wood is expected to be used for 50 or more years, preservatives might be leached by rain and water, or components may be lost by evaporation (mainly organic substances); in addition, interactions between wood or organisms and the preservative could lead to a lowering of activity. Qualitative chemical analysis is an effective instrument for determining the causes of these losses. Since about the 1980s, analytical procedures have become particularly important as regards disposal of wood treated with preservatives, the testing of soil polluted with wood preservative residues (e.g., in impregnating plants), and the possible discharge of active substances from treated wood into water, soil, and air.

Qualitative Analysis. Colorimetric reactions are frequently used for qualitative detection (and depth of penetration) of water-soluble *inorganic salt preservatives* based on copper salts, fluorides, chromium(III) (fixed form), arsenic salts, boric acid, and borates, [137, 138]. In *creosote impregnation*, besides the characteristic odor, the brown to black coloration of the wood provides a means of optical recognition. Many methods have been proposed for the analysis of coal-tar creosote [139]. *Organic active substances* cannot be detected by a simple color reaction. The Beilstein test [140], frequently used for detecting PCP and lindane, is a nonspecific method of detecting halogen compounds.

Quantitative Analysis. For the quantitative analysis of wood preservatives, sampling is particularly important [141]. *Inorganic elements* are detected after extraction from the wood or in the residue after incineration of the wood. For the determination of metals, atomic absorption spectroscopy [142] and X-ray fluorescence spectroscopy [143, 144], for example, are employed. Colorimetry can be utilized for the determination of boron [145], and for fluorides the ion-selective fluoride electrode. For larger quantities of these elements, classical analytical methods can also be used.

Organic preservatives are generally determined, after extraction from wood, by using various chromatographic methods. Thin layer chromatography with a subsequent color reaction has proved effective for qualitative detection of active substances [146 – 148]. For direct detection and semiquantitative determination of substances such as PCP, dichlofluanid, tebuconazole, propiconazole, and permethrin in wood, GC–MS coupled methods using pyrolysis gas chromatography followed by a mass-selective detector are suitable [149].

7. Processes for Applying Wood Preservatives

7.1. Overview

Most types of wood are subject to attack or damage by wood-destroying fungi, insects, or marine animals if they are exposed to environmental conditions that favor the growth and development of these pests. Some types of wood possess natural durability. However, others (e.g., many of the most frequently used softwoods) are very susceptible. European standard EN 350, part 2, gives the natural durability and ease of impregnation of a selection of wood types that are important in Europe [150]. In other areas (e.g., Japan), similar data have been compiled [151, 152]. In general, wood preservatives are used as a precautionary measure to protect healthy wood. This also applies to flame retardants. The preservative is applied to the wood to as great a depth as possible. An exception is the temporary protection of wood against insects and wood-discoloring fungi after felling, during transport, and in storage areas during air drying.

Many processes for applying preservatives are available. In processes using reduced or excess pressure the preservatives penetrate into the wood because of the pressure differences. The

pressure process and the low-pressure process belong to this category. In pressure-free processes, the capillary forces in wood tissues are responsible for the absorption of preservative solutions. Pressure-free processes are used as either long- or short-term processes. With the latter, only surface protection of the wood is achieved.

Before wood is treated with preservatives, the bark and phloem must be removed. Also, the treatment should occur only after the final machining process. For sap displacement procedures the presence of bark is essential for the process (see Section 7.2.2.2). Because of the different ease of impregnation of various woods, the degree of impregnation aimed at also varies. Heartwood and mature wood are generally much more difficult or nearly impossible to impregnate compared with sapwood [135, 153, 154].

The choice of preservative, impregnating process, impregnating conditions, quantities applied, and minimum efficiency in biological experiments is laid down in EN 599, part 1, within the framework of the European standards for wood preservation [155]. The demands made on wood preservatives, as determined by biological experiments, are described in EN 599, part 2 [156]. With regard to the use of wood preservatives, five possible biological hazard classes are defined in EN 335, parts 1 and 2 [157, 158]. They are listed in Table 6. Wood in hazard classes 4 and 5 generally needs to be treated by using the pressure impregnation process.

Factors affecting the results include the following:

1) The preservative-absorbing capacity and ease of impregnation of a particular type of wood
2) The moisture content of the wood at the time of surface treatment of impregnation
3) The application or impregnation process used
4) The physical properties of the preservative, such as solubility, penetrating capacity, corrosion properties, behavior on temperature change, viscosity, suitability for certain processes, and odor.

Measures for wood attacked by fungi or wood infested by insects are carried out predominantly on wood that has already been used in construction. If the attack is not too severe, particularly inside the wood it can be dealt with by boring holes and using suitable preservatives, for example in poles, beams, or window frames. Badly damaged pieces of wood and construction elements that have been severely weakened in their static properties must be replaced by new ones treated with preservatives.

Depending on the area of use, wood species, its natural durability and ease of impregnation, and the impregnation process and preservative employed, treated wood can be used for 3 to >20 years longer than untreated wood [159]. Thus, properly carried out wood preservation is very economical.

7.2. Processes Using High or Low Pressure

Pressure processes have been used for more than 150 years for impregnating wood with preservatives. The distribution of preservative should be as deep and uniform as possible in the parts of the wood that can be impregnated. Heartwood generally absorbs very little preservative. Different types of wood vary in their ease of impregnation. Treatment using the pressure process is absolutely necessary for wood in constant contact with water or soil. The process is often employed also for treating wood used outdoors in frequent contact with water.

The choice of pressure process depends on the intended use, the nature and quantity of the preservative, and the moisture level of the wood at the time of treatment.

Reduced pressure (vacuum) processes are used for treating dried construction wood, in particular, with solvent-containing preservatives (*double vacuum*). Water-soluble preservatives (*simple vacuum*) are also suitable for this process. Higher penetration depths are achieved than with the dipping process, and less preservative is used than with the pressure process. Vacuum impregnation is not suitable for wood that is in continuous contact with water or soil. Green wood (e.g., poles or roundwood) can be impregnated with salt preservative solutions by sap displacement.

7.2.1. Pressure Process

The basic equipment for a plant for the *full-cell process* consists of an impregnating cylin-

Table 6. Definition of biological hazard classes for solid timber

Hazard class	Situation in service	Description of exposure	Wood moisture content
1	above ground, covered (dry)	permanently dry	permanently 18 %
2	above ground, covered (risk of wetting)	occasionally wet	occasionally 20 %
3	above ground, not covered	frequently wet	frequently 20 %
4	in contact with ground or fresh water	permanently wet	permanently 20 %
5	in salt water	permanently in salt water	permanently 20 %

Figure 1. Schematic of a plant for the full-cell process
a) Impregnating cylinder; b) Vacuum pump; c) Pressure pump; d) Storage and measuring vessel; e) Dissolving vessel for water-soluble preservatives

der with one or two seals, one or more storage vessels for various wood preservatives or solutions of different concentrations, a pressure pump, a vacuum pump, measuring and dissolving vessels, and a control device for maintaining impregnation conditions. Plants for the Rüping process also include a compressor and a pressurizable storage vessel.

The pressure process gives the best preservative distribution in wood. Water-soluble salts, creosote, and mineral oils with fungicides or insecticides are used.

Full-Cell Process (Fig. 1). In the full-cell process (saturation impregnation or vacuum–pressure impregnation), air present in the wood is removed with a high initial vacuum, then the impregnation cylinder is filled with the preservative solution while the vacuum is maintained. Finally, after air is admitted to the cylinder, an impregnation pressure is produced and maintained for a defined period, depending on the ease of impregnation of the wood. Generally pressures >0.9 MPa are applied. The pressure is maintained until virtually no more liquid is absorbed by the wood. In some plants this is controlled automatically via an end-phase counter, which determines the quantity of preservative that can still be absorbed by the wood. Application of a short final vacuum should decrease the extent of dripping of the impregnating solution from the wood after it is removed from the cylinder. This process was introduced by Bréant in 1831 for impregnation with salts, and by Bethell in 1838 for impregnation with tar oils. Figure 2 shows an impregnation diagram for the full-cell process. Most plants are now controlled automatically with fixed programs and can produce full impregnation protocols independently.

Figure 2. Pressure diagram for the full-cell process

Figure 3. Schematic of a plant for the Rüping process
a) Vacuum pump; b) Air compressor; c) Measuring vessel; d) Pressure pump; e) Storage vessel; f) Impregnating cylinder

The full-cell process is applied mainly for water-soluble wood preservatives. Coal-tar oils and solvent-containing preparations are seldom used because preservative absorption is too high. The absorption of liquid is between 100 L/m^3 (spruce poles) and 500–600 L/m^3 (pine boards or posts), depending on the type of wood, thickness in the case of sawn timber or roundwood, and pretreatment (e.g., perforation of spruce).

Empty-Cell Processes. In 1902 and 1906, respectively, Rüping and Lowry developed processes that allowed absorption of a smaller amount of liquid in the pressure process without impairing impregnation. The processes are known as the empty-cell processes and are used, in particular, for hot creosote oils. Here, only the endangered cell walls are treated with preservative, while the cell cavities remain empty.

Rüping Process. In the Rüping process (see Fig. 3), air present in the cells is first compressed and absorption of liquid is thus prevented. The impregnation cylinder is then filled with preservative while the initial air pressure is maintained and an impregnating pressure (generally >0.9 MPa) is produced and maintained over a defined period. The cylinder is then depressurized to atmospheric pressure. During depressurization, air in the wood, which has been compressed in the prepressure stage and further during impregnation, expands and expels a considerable portion of the preservative from the wood cells. This is then recycled to the storage vessel. Subsequently as high a final vacuum as possible is produced, which results in a second expulsion of preservative. After the cylinder has been aerated to return it to atmospheric pressure, the impregnating solution recovered during the final vacuum is also recycled to the storage vessel. Figure 4 shows the impregnation diagram for the *simple Rüping process*.

Figure 4. Pressure diagram for the Rüping process

The simple Rüping process is suitable for impregnating softwoods, such as pine, spruce, larch, fir, and Douglas fir, and some hardwoods such as beech. The average quantities of creosote absorbed are, for example, for beech railway ties ca. 175 kg/m^3; for pine railway ties, ca. 60 kg/m^3; and for pine poles or pine, spruce, larch, fir, or Douglas fir posts, ca. 90 kg/m^3. Both tar oils and water-soluble salt mixtures can be used in the Rüping process [160].

Railway ties that are difficult to impregnate can be treated satisfactorily with creosote using the *double Rüping process*, which involves a combination of two simple Rüping impregnations. Improved Rüping processes with *preconditioning* are used only for impregnation with creosote and give a considerably improved tar oil distribution in the wood [161]. The coal-tar creosote is heated to the prescribed impregnation

temperature before the beginning of the pressure period. In a preconditioning phase the impregnating cylinder is filled with hot creosote at 115–120 °C. After cooling the creosote on the wood, the former is heated again to at least 100 °C. This temperature is maintained until the wood is sufficiently prewarmed. The lower viscosity of the creosote achieved by these measures allows more rapid penetration of the preservative and better distribution in areas of the wood that can be impregnated. Both the simple and the double Rüping processes can be improved by preconditioning. In 1986, the improved double Rüping process was simplified by omitting the intermediate vacuum after the first compression period.

Lowry Empty-Cell Process. Unlike the Rüping process, the Lowry empty-cell process does not employ preliminary air compression [162]. After the wood has been charged to the impregnating cylinder, the latter is filled with impregnating liquid at atmospheric pressure. Pressure is then applied, and the length of the compression period can vary depending on the type of wood and its dimensions. As in the Rüping process, impregnation is terminated with as high a final vacuum as possible. However, the quantity of liquid expelled is less than in the Rüping process. Creosote and waterborne salt preservatives are used in this process.

Rotating-Vessel Process. The rotating-vessel process is an extension of the pressure process and was introduced by Poulain in 1938. It is used in some European countries, for example, to doubly protect poles that have already been impregnated with salt preservative solutions, with coal-tar oil in the particularly vulnerable lower sections. Here, the impregnating cylinder, which is charged in a horizontal position, is moved to a vertical position before beginning the impregnation process. Since salt-impregnated poles must be predried for several weeks before rotating-vessel impregnation with creosote, treatment of the lower sections with creosote is often carried out beforehand.

Liquid-Gas Process. The liquid-gas or Cellon process is a further variant of the full-cell process. It was developed by Hudson and is used mainly in the United States [163 – 165]. Active substances, mostly PCP [135], dissolved in liquefied petroleum gas (isobutane—butane) are charged to the evacuated impregnating cylinder, and the impregnating pressure is produced by increasing the temperature of the liquid to 20–30 °C. By gradually lowering the pressure to atmospheric and subsequent evacuation, most of the liquefied petroleum gas is recovered, while the preservative remains in the wood. The process has the advantage that the wood is obtained dry and, particularly for hardwoods, a deeper and more uniform penetration of the active substance is possible. Impregnation requires special safety measures and additional equipment for recovery of liquefied petroleum gas.

Oscillating Pressure Method. To impregnate green cordwood, particularly roundwood that is difficult to treat in the dry state, the oscillating pressure method was developed [166]. Only waterborne preservatives are used. In principle, the process can be carried out in any pressure plant, provided that automatic plant control for cyclic pressure changes is available. An oscillating pressure plant is shown schematically in Figure 5. In this process, vacuum and pressure phases alternate, whereby the phase changeover occurs in less than one second. During the vacuum phases a small quantity of liquid is sucked out of the wood, and in the compression phases the salt solution is pressed in. As the impregnation period continues the pressure phases increase in length. For example, with green spruce, ca. 400 phase changes occur during the ca. 22-h impregnation process. Here the sap still present in the wood is continuously replaced by preservative liquid with an increase in the impregnation of the sapwood. For wood that is difficult to impregnate, the oscillating pressure method gives better impregnation and greater penetration depths than the full-cell method [167].

In a variation of the oscillating pressure method, the usual vacuum phases are omitted [168, 169]. In intervals of minutes, pressure is produced slowly in the cylinder, maintained for a short time, and then reduced to atmospheric again. The length of the cycles is of the order of minutes and remains constant during the impregnation process. The number of cycles is considerably fewer than in the conventional oscillating pressure process. By using the air compressed in the wood, the sap is continually enriched and replaced by salt preservative solution.

Supercritical Carbon Dioxide. The use of a supercritical fluid for the impregnation of wood with organic fungicides and insecticides under high pressure ($\geq$ 10 MPa) is a new technology which was commercialized first in 2001 in Denmark [170]. Advantages of this process include short impregnation cycles, avoidance of volatile solvents and water (long drying time; dimensional changes), and enabling the treatment of wood species that are resistant to conventional processes [171]. In addition, the treatment of wood-based composites (e.g., oriented structural board (OSB), medium-density fiberboard (MDF), plywood, laminated veneer lumber (LVL)) offers a large potential for the utilization of the supercritical carbon dioxide technology [172].

7.2.2. Low-Pressure Processes

7.2.2.1. Low-Pressure Processes for Dry Wood

Simple Vacuum Process. In the simple vacuum process, which is no longer important, the wood is charged to the impregnating vessel and as much air as possible is removed from the wood tissue by using a vacuum pump. The impregnation itself is then carried out at atmospheric pressure. Preservative dripping off the wood is collected.

Double Vacuum Process. The double vacuum process allows the economical use of solventborne wood preservatives because excess preservative can be recovered from treated wood and recycled by means of the second vacuum, which is applied at the end of the impregnation process. The first stage is carried out as in the simple impregnation process. For wood that is not readily impregnated (e.g., spruce or Douglas fir), the pressure difference between the initial vacuum and atmospheric pressure is not sufficient to allow the required quantity of preservative to be applied. In this case a modification of the Lowry process can be used, in which the preservative is absorbed under impregnating pressures of 0.2–0.6 MPa. On using this process, depths of penetration are achieved that lie between those of the dipping and the pressure processes.

The double vacuum process is used mainly for wood that must not swell any more after drying. This includes, for example, building components that have been planed or must have an exact size, such as windows, doors, and outside claddings. The advantage of the process that, after evaporation of the solvent, decorative var-

nishes or paints can be applied. Glueing is also possible. Other components, such as hydrophobing agents, can be added to the wood preservatives developed for the vacuum process.

To decrease pollution by solvents, solutions of water-soluble preservatives are now also used in the vacuum process.

7.2.2.2. Low-Pressure Process for Green Wood (Sap Replacement Process)

In the sap replacement process, which was introduced in 1838 by Boucherie, the sap in freshly felled, nondebarked conifers is replaced by a water-soluble salt preservative solution. From this, Gewecke developed the tank suction process in which debarked, green roundwood is placed in an impregnating tank equipped at one or both ends with a suction cap and attached by tubing to a vacuum pump [173]. The sap is sucked from the trunk by a high vacuum and is replaced by the salt preservative solution from the tank, which penetrates through the surface area of the wood [174 – 176]. A variant of this process is the tank pressure suction process developed by Gruber, in which sap is sucked from the top end and replaced by the salt preservative solution in the tank [177]. At the bottom, salt preservative solution at a higher concentration is pumped into the wood from an additional storage container by using a pressure pump.

Despite various improvements [e.g., the cap developed by Bundesanstalt für Materialforschung und -prüfung (BAM cap) [174], sap replacement processes have been superseded by the oscillating pressure process [167] because of shorter impregnating times and more reliable impregnation.

7.3. Pressure-Free Processes

In pressure-free processes, no plants with pressure vessels and pressure or vacuum pumps are necessary for applying the preservative. The wood absorbs preservative solutions through capillary forces and diffusion. Penetration of the preservative can also be promoted by the hydrostatic pressure of the liquid covering the wood in the impregnating container and by temperature differences in the impregnating liquids (hot–cold).

7.3.1. Long-Term Processes

Diffusion Process. In the diffusion process, which is used in only a few countries, peeled or sawn green wood is treated with highly concentrated solutions or pastes of water-soluble salt preservatives. After dipping or brushing on of preservative, the moist wood is piled up, coated with a watertight cover, and stored for several weeks. A good degree of protection is achieved even in wood that is difficult to impregnate, such as spruce or fir, by diffusion of the active substances. Borates are being used increasingly for this process [178 – 180]. At the end of the diffusion process the wood is dried or stored until dry. The disadvantage of this process is that the preservative is not fixed in the wood and can therefore be leached out. In a *double diffusion process* [181, 182], debarked, moist wood is first placed in a waterborne salt preservative solution, frequently copper sulfate, for several days and then impregnated with another salt solution, such as sodium chromate or dichromate, also for several days. Copper sulfate and chromate react to form a water-insoluble precipitate. Treated wood must be dried before use. This process is frequently used where no impregnating plants are available.

Open tank impregnation is still widely used. Here, semidry to dry wood is immersed completely in preservative solutions, which can be diluted with water, for up to several days. The process was introduced in 1832 by Kyan for treating wood with mercuric chloride solutions (kyanization). The use of mercury is now prohibited almost worldwide. Only surface protection of wood is generally achieved. Deep protection is also possible with readily impregnated or moist wood. A disadvantage is that uniform absorption is not guaranteed when salt preservative solutions with several components are used.

Hot–cold open tank impregnation is a variant of tank impregnation. In this process the impregnation period can be shortened and the depth of penetration increased. It is particularly suitable for creosote impregnating oils. Because water-soluble wood preservatives can be applied

at 50 °C (max.), they are not used for this process. The principle underlying the process is the fact that on storing dry to semidry wood in warm impregnating liquid, air present in the wood expands. On subsequent cooling, slight subatmospheric pressure develops in the wood, depending on the temperature difference. Because of this subatmospheric pressure, more impregnating liquid can be absorbed by the wood. Heating and cooling the impregnating liquid can be carried out in either the same or two separate tanks. In using creosote impregnating oil, the preservative and the wood are heated to ca. 80–110 °C and this temperature is maintained for several hours. It is then lowered to ca. 40–50 °C, either by replacing the hot solution with a cold one or by transferring the wood to a tank containing cold solution. The hot–cold open tank impregnation can be modified for the use of heat-sensitive preservatives or those based on flammable solvents. In this case, wood is heated for 1–2 h by, for example, hot water, hot steam, or hot air, and then transferred as rapidly as possible to a tank containing cold preservative solution, where it is cooled.

A variation of the tank and hot–cold open tank impregnation processes is *butt-end treatment*, which is frequently used for preserving fence, fruit tree, and vine posts, and similar objects, in areas where they are in contact with soil. Wooden posts are placed vertically in vessels containing creosote, in which the oil level is 20–30 cm above the envisaged depth of immersion in the soil. The vessels are then heated to >100 °C. Impregnation occurs during the cooling-down phase. Water-soluble or solvent-containing preservatives are used only for impregnating solutions where the temperature is not raised. Depending on its moisture level, the wood can remain from days to weeks in the solution.

7.3.2. Short-Term Processes

Short-term processes are wood treatment methods that are easily carried out and generally do not require expensive equipment. The preservative solution is applied to the wood surface only once or twice. Since preservatives penetrate the wood to a maximum of a few millimeters, only surface protection is achieved. These processes are therefore suitable only for wood that is not exposed to any particular hazard.

The simplest treatment methods are *brushing* and *spraying*. Spraying should be carried out only if precautionary measures are taken with regard to environmental safety and health. Solvent-containing preparations and oily formulations that can be diluted with water are mainly used. The quantity of preservative absorbed essentially depends on the type of wood and the nature of its surface. Two treatments are generally necessary. If water-soluble preservatives are used, wet-in-wet processing is generally employed to achieve greater depths of penetration.

Deluging. A further development of the spraying process is the deluging process, in which dry wood is stored above a receptacle and the preservative solution is allowed to flow over it. Excess solution is collected in the receptacle and pumped back to the storage tank. Since the upper and lower sides of the wood need to be treated, two operations are necessary. The process has the advantage that no spray mist is formed.

Spray Tunnel Plants. The use of spray tunnel plants permits the uniform application of preservatives, while minimizing their waste. Both mobile and stationary plants exist. In these plants, dry wood is passed continuously through a spray chamber. The jets are arranged such that the wood is sprayed uniformly on all sides. Excess preservative solution and that dripping off are collected and can be reused. A device that scrapes off preservative not absorbed is generally placed after the spray tunnel to minimize loss through dripping after the wood has left the tunnel. As with other short-term processes, the absorption of solution and thus the quantity applied depend on the type of wood, the nature of the surface, and sometimes the moisture level in the wood. Higher depths of penetration can be achieved by mechanical pretreatment of the wood, for example, by oblong perforation.

Short-Term Dipping. In short-term dipping, wood is dipped for a short period into a vessel containing a preservative solution, usually via a lifting device. The advantage of this process is that the wood comes into contact with preservative on all sides. Depending on

the type of wood, the way it is worked, and the formulation of the preservative, varying quantities are absorbed. For some preparations, repeated dipping is necessary to achieve sufficient protection. The process is used, in particular, for joinery (e.g., in window production). Both solvent-containing and waterborne preservatives are used.

7.4. Preservation of Wood-Based Materials

Particle board, veneer plywood, laminated plywood, and fiberboard can be attacked and destroyed by fungi. However, the use of chemical preservatives is sensible only if the adhesives used in the production of these wood materials—e.g., alkaline-hardening phenoplastics, aminoplastics reinforced with phenol–resorcinol resins (melamine–urea–phenol–formaldehyde MUPF), or polymeric diphenylmethane diisocyanates (PMDI)—are sufficiently resistant even at high wood moisture levels. In temperate climates, plywood needs to be protected against insects if it is made from tropical woods such as abachi or limba. In the tropics and similarly warm areas, plywood and particle or fiberboard can be damaged by insects, including termites.

7.4.1. Treatment with Preservatives during Production

In *particle board* production, mixing the preservative with the adhesive is the preferred method. Formulations or powders that can be diluted with water, highly concentrated salt solutions, or solvent-borne preparations are mixed with adhesive and other additives and sprayed onto the particles. If the preservative and adhesive cannot be mixed for technical reasons, they can be applied to the particles separately, for example, in the mixer. Also, preservatives in powder form can be mixed with glue-blended particles and dispersed. In the production of *veneer plywood boards*, the preservative is also generally mixed with the adhesive. The quantity of preservative added depends on the construction of the board (i.e., number of veneers and quantity of adhesive applied). Since the preservative must penetrate the veneers from the adhesive seam, use of this process depends on the thickness of the veneers. Veneered laminated boards with thicker veneers can be treated with preservative after production (see Section 7.4.2).

For *laminated plywood* (laminated board, blockboard), strips and face veneers can also be treated by dipping or spraying if penetration of the preservative is sufficient. Otherwise, the strips must be treated by using a pressure process. After impregnated wood has been dried, adhesive is applied and the boards are pressed together.

Treatment of *fiberboard* by adding preservative to the pulp slurry causes problems in the commonly used wet process because the active substance if partly lost when water is pressed out [183].

7.4.2. Treatment with Preservatives after Production

After production, *plywood and veneer plywood* can be impregnated under pressure with salt solutions or solvent-containing preparations. However, the disadvantage is that because of moisture absorption, drying is necessary before processing can be carried out. In another method, trimmed boards, which are still warm from the press, are treated by dipping in an aqueous preservative solution. However, care must be taken so that the boards do not warp.

Fiberboard can be treated after production with aqueous or solvent-containing preservatives by dipping or pouring [184, 185].

7.5. Special Processes

Special processes are used if:

1) After a long period of use the original preservative content needs to be supplemented or increased in building (e.g., beams)
2) The depth of penetration and distribution of the preservative needs to be improved in wood that is not easily impregnated (e.g., spruce or fir)
3) Protection of wood used in building against fungi or insects is required, which cannot be achieved with usual impregnating processes

4) Areas that are particularly at risk (e.g., wood in the below/aboveground zone) need additional protection
5) Only partial wood preservation measures are required (e.g., protection of the ends of joists)

Protection with Bandages. Poles (e.g., for electric and telephone transmission) should exhibit long-term durability. The below/aboveground zone of these poles, which is particularly at risk from attack by fungi (predominantly soft rot fungi), can be protected by bandages. waterborne wood preservatives (e.g., based on fluorine or boron) can be worked into the carriers of these bandages, which are made of foam or other porous materials. The moisture present in roundwood allows deep penetration of preservative. The 50–70 cm-wide bandages are placed around the poles in one piece and generally renewed at intervals of five to ten years. For subsequent treatment or for increased protection in the below/aboveground zone, the injection process (Cobra process) has proved effective [186]. A hollow needle is injected into the wood to a depth of a few centimeters at defined intervals, and a water-soluble salt preservative paste is pressed into the wood through the needle. The preservative is dispersed in the wood by diffusion.

Incising Processes. To improve the depth of penetration and dispersion of preservative in wood that is difficult to impregnate, various incising (perforation) processes are used [187]. The perforations can be made by using rotating or fixed needles or piercing knives. The depth of piercing is generally 10 mm or more [188]. For planed wood, the depth is much less [189 – 191]. Laser processes have also been proposed for perforation [192, 193].

Bored-hole processes are used when building components cannot be impregnated sufficiently by brushing or spraying (e.g., in case of attack by insects) or when beam joints, footings, and beams in contact with walls and soil, or buried palisade wood, are endangered by the action of moisture. The wood is generally bored downward at an angle. The bored holes, with a diameter of 8–15 mm, are filled with a preservative one or more times and plugged. To impregnate as large an area as possible, pressers are frequently used. Here preservative is pressed into the wood by compressed air via a hollow drill. Solid salt cartridges (die-pressed pieces) (e.g., based on boron or fluorine) are used in bore holes for the posttreatment of damp wood or wood that is becoming damp. The active substance is then dispersed by diffusion [194]. To control wood-destroying fungi in window frames, this type of treatment using boron-based cartridges and fluoride injection has proved successful [195 – 197].

Foam Process. By using the foam process, wood can be made to absorb relatively large quantities of preservative in a short time [198]. Water, which contains the dissolved preservative, is foamed after the addition of a surfactant. The foam is applied to the wood and breaks down slowly, whereby the active substances penetrate the wood. The process is used for prevention of and combating attack by pests.

For the use of agents that are active in the gas phase (fumigants) and can be used, in particular, to control wood-destroying fungi inside wooden poles, see Section 2.5.

8. Environmental Aspects

8.1. Health Aspects

Like plant protection agents, wood preservatives are assessed by health and environmental authorities with regard to their acute, subchronic, and chronic toxicity. During production and use of preservatives and their mixtures, direct contact (e.g., via dust, vapors, aerosols, and spray mists) cannot be excluded. Thus, investigations on possible carcinogenicity [e.g., of arsenic and chromium(VI) compounds or BaP in coal-tar oil], mutagenicity, or teratogenicity are particularly important. Knowledge of the maximum concentration at the workplace (MAK, TLV) is also important. Since wood preservatives are also used in inhabited indoor areas, evaluation of the effect on occupants through liberation of active substances from preserved wood is particularly important (see Section 8.2).

8.2. Soil, Water, and Air

Besides investigating the toxicology of wood preservatives, the quantities of active substances

that can get into the soil or water by leaching and into the air by evaporation must also be known. These proportions depend on the application process and the quantity applied to the wood. For organic active substances and coal-tar oil components, investigations on the behavior in soil and on biodegradability (partial or complete) are important. For partial degradation the metabolites should be identified if possible. Other criteria for risk assessment could be adsorption or desorption on soils and sediment, degradation and metabolism in water–sediment systems under anaerobic conditions, and bioaccumulation. With regard to the risk estimation for ground-, drinking, and surface water, knowledge of the percolating and mobility behavior of active substances (in some cases, their metabolites), inorganic salts, and salt mixtures is important. In the case of salts and salt mixtures, boron, fluorine, and the heavy metals arsenic, chromium, and copper play an important role. They can be leached out of treated wood or enter soil because of poor operational hygiene in impregnating plants or during open tank impregnation. In most countries, tests of possible harmful effects on aquatic or terrestrial organisms are required for the ecotoxicological evaluation of wood preservatives. The fish toxicity test [199] can, for example, be carried out according to OECD Test Guideline 203, Testing Guidelines for Chemicals [200]. Depending on use, investigations of the effects of wood preservatives on pets, working, and other animals and on ornamental, useful, and other plants may be necessary.

A five-year observation period of poles impregnated with creosote established that the components that had leaked out had obviously been degraded by microorganisms because they could no longer be detected [201]. *Pseudomonas* strains, in particular, are thought to be involved in biodegradation [202, 203]. For wood that is used in contact with water, a severe effect on the taste of fish and water was established due to the washing out of phenols and other water-soluble compounds. Even traces make fish unpalatable [204].

Wood impregnated with Cu–Cr–As is particularly resistant to leaching and weathering, compared with other chromium-based salt preservative combinations, such as F–Cr–As, Cu–Cr–F, Cu–Cr–B, and Cu–Cr. However, arsenic, copper, and chromium can be leached out in varying quantities. The degree of mobility and the bioavailability of these elements are affected by the type and structure of the soil and the pH [205 – 214]. Fluorine and boron can be leached out relatively easily [215].

Acid rain has little effect on the leaching of copper, chromium, or arsenic, as model experiments on Cu–Cr–As-impregnated wood have shown. At pH 3.0, copper and arsenic are leached out to a greater, and chromium to a lesser, degree [216, 217].

Environmental pollution by preservative components, particularly in impregnating and dipping plants, has to some extent impaired soil and both ground- and drinking water [218 – 220]. Considerable quantities of preservative components [e.g., toxicologically harmful chromium(VI) compounds or arsenic] can enter the environment before they are fixed in the wood through dripping or the action of rain. Salt preservatives can enter soil or wastewater from wood that has been impregnated with water-soluble boron salts or with silico- or hydrogenfluorides, if it is stored unprotected.

To avoid dripping of unfixed preservative solution containing chromate(VI) from impregnated wood, the fixing period can be reduced from 8–30 d to less than 1 h, for example, by using steam at 110 °C [221]. Chromium(III) compounds formed in the fixing process are considered less toxic than chromium(VI) compounds.

Impregnating plants, dipping tanks, and drip collection installations for wood treated with preservatives must be erected on reinforced areas with the appropriate collecting equipment for excess preservative, and stored impregnated wood must be protected from rain for environmental reasons. Impregnating tanks, dipping tanks, spraying tunnels, piping, and pumps must be watertight, and wastewater must be disposed of correctly. For example, no preservative-containing solution should be passed into wastewater channels or sewage plants.

In the European Union and in countries like the United States and Canada, health/environmental authorities require an exhaustive risk assessment of health and environmental impacts not only for the treated wood in-service, but also for production and processing of wood preservatives, for example, in impregnating plants. For certain areas of use, inves-

tigations into the possible absorption of active substances by foods can be required.

No standard test procedures have yet been worked out that stipulate conditions for determination of the concentration of active substances that can be regarded as posing no risk to health indoors.

For risk assessment, the volatility and vapor pressure of the active substance and its acute or subchronic inhalation toxicity, as well as the acute LC_{50} for inhalation of a formulation of this substance, can be determined.

In association with the evaporation of wood preservatives, particularly organic compounds from treated interior surfaces [222], various models for risk assessment with regard to possible health hazards have been developed in Europe [223]. Insecticides or fungicides emitted to the air can be absorbed by humans through inhalation. This can take place over several years.

In long-term tests at 20 °C the concentrations of lindane, endosulfane, dichlofluanid, and pentachlorophenol in the air of living rooms were determined by gas chromatography. The type of wood and associated depth of penetration of preservative, the surface area : room space ratio, and the air exchange rate had a significant effect on the concentration of active substances [224].

Risk assessment can be expressed in terms of the following formula:

$$\text{Acceptable air concentration (AAC)} = \frac{\text{acceptable daily intake (ADI)}}{V}$$

where V is the volume of air that is inhaled by a human of 70 kg weight over 24 h; this is assumed to be 18.5 m^3 [225, 226]. ADI values have a safety margin of 100.

8.3. Disposal of Treated Wood

The disposal of wood treated with preservatives is very important with regard to environmental pollution. For example, the inorganic preservatives arsenic, chromium, copper, and mercury, and the organic preservatives pentachlorophenol, other chlorinated cyclic compounds (e.g., chloronaphthalene, endosulfane, and lindane), and coal-tar oil pose a particular hazard to the environment. In many countries, particularly Germany [227], laws and regulations have been drawn up that must be adhered to in the disposal of treated wood.

At the end of its service life, treated wood becomes waste wood. This category also includes waste pieces produced during production and processing. The choice of disposal method depends on the polluting potential of the preservative and the amount of it in the wood. Color reactions can be used to detect inorganic compounds [137], but generally not organic ones. The Beilstein test, frequently described in the literature for detecting pentachlorophenol and other halogen-containing compounds, is not very reliable [140]. A specific test has been developed for pentachlorophenol itself [227]. In quantitative analyses (see Chap. 6), the sampling procedure before actual analysis is important for obtaining a representative result [141, 228].

Recycling. The recycling of treated waste wood is very limited. Railway ties that are no longer suitable for a main line can still be used for a long period on a branch line, where they are less stressed. Electricity poles can be used as fence posts and railway ties in embankments [229].

For large wooden objects such as poles, railway ties, and girders, the outer layers of wood treated with preservative can be removed and incinerated. The remaining wood, which is largely preservative free, can then be reused.

Disposal. The disposal of treated wood in dumps can be problematic if preservative components are leached out or liberated through degradation of the wood, thus polluting soil, groundwater, or air.

According to the current state of the art, *incineration* is the best form of disposal for wood treated with preservatives. The important prerequisites for this are an incineration technique that allows almost complete combustion and effective dust collection to minimize emissions.

Inorganic preservatives are not destroyed by incineration. Arsenic [230] and fluorine are particularly important since they enter flue gas because of their volatility and are more difficult to collect by dust separation than chromium and copper, which remain in the ash and the filter.

Boron-containing preservatives can lower the melting point of the ash considerably. This can lead to corrosion and slag problems in the incineration chamber [231]. Boric acid itself can evaporate together with the steam produced in incineration.

When wood treated with creosote is mixed with untreated wood in the ratio 1 : 4, under optimum incineration conditions the concentrations of CO, NO_x, and hydrocarbons are in the same range as those found for untreated wood [232].

Organic aromatic substances containing a variety of heteroatoms in the ring can be assumed to be more readily degraded thermally and oxidatively than others, such as pentachlorophenol. The formation of PCDDs and polychlorinated dibenzofurans (PCDFs) during incineration of PCP-treated wood can be kept low by using temperatures >500 °C and a good air supply [231, 233].

A new direction of research is *biological disposal* of wood treated with salt preservatives by the use of selected microorganisms with special physiological properties. The aim of this method is to recover heavy metals such as arsenic, chromium, and sometimes copper. The leached wood can then be disposed of in a dump or composted [234].

Promising experiments have been carried out in which chromate-containing preservatives have been converted into a water-soluble form by the use of inorganic and organic acids and then washed out of the wood [235 – 237].

1. Introduction

Being a natural raw material, wood is anisotropic and inhomogeneous; it has a porous cell structure, which can be swelled by water (→ Wood, Chap. 1.4.). Chemically, wood consists of a framework of cellulose, together with lignin (which imparts rigidity to the cell walls and acts as a binder) and hemicelluloses. Dyes, resins, fats, and water are contained in varying quantities (→ Wood, Chap. 1.3.1.). Wood has been used for hundreds of years as a building material and for items of daily use. It is unique in its color and surface structure.

Wood and wood products are sensitive to many external influences. These include animal pests, fungi, discoloration by sunlight, and changes effected by water, atmospheric moisture, and many other substances in daily use. Changes in environmental conditions bring about dimensional changes in wooden objects.

Wood and wooden objects must be protected against these influences by impregnating or coating if their usefulness is to be maintained. Because of the anisotropic nature of wood, surface coatings must have specific properties. The requirements of coatings for wood and wood products for outdoor use differ fundamentally from those for indoor use.

Coatings for Outdoor Use. Outdoors, solid wood is used primarily and generally coated with materials having insulating and impregnating properties. Here, no actual film is formed on the surface. The coatings also contain substances that repel pests (see → Wood, Preservation).

Coatings for Indoor Use. The processing conditions and use of paints and coatings for interior decoration and furniture are completely different. Indoors, solid wood and wood products of the most widely differing varieties are used, e.g., particle board (sheeted, veneered), medium-density fiber (MDF), and other fiber boards, and plywood (→ Wood, Chap. 2.2., → Wood, Chap. 2.3.).

In processing wood for the production of furniture and interior decoration, the original color and surface structure (pore structure), which are characteristic of the type of wood used, are included in the design of the surface. In surface treatment, the coating is either open or closed cell, but some overlap can be found between the two types.

Before surface treatment can be carried out, wood and wood products must be subjected to many preliminary processes, such as shaping (particularly for solid wood articles) and grinding with reducing grades of abrasives. Depending on the use envisaged, furniture must also fulfill certain criteria. For example, kitchen equipment (e.g., work surfaces) requires a higher level of resistance than other furniture. The different requirements determine the choice of coating system.

Coating systems for furniture and interior decoration are compiled in Table 1; common solvents for paints are listed below:

Alcohols
Ethanol [*64-17-5*]
Isopropanol [*67-63-0*]
Butanol [*71-36-3*]
Isomeric butanols

Esters
Ethyl acetate [*141-78-6*]
Isopropyl acetate [*108-21-4*]
Butyl acetate [*123-86-4*]
Isomeric butyl acetates

Aromatic hydrocarbons
Toluene [*108-88-3*]
Xylene [*1330-20-7*]

Aliphatic hydrocarbons
Naphtha fractions with various boiling ranges

Ketones
Acetone [*67-64-1*]
Methyl ethyl ketone [*78-93-3*]

Glycols and derivatives
1-Methoxy-2-propanol [*107-98-2*]
1-Methoxyprop-2-yl acetate [*108-65-6*]
Butyl glycol [*111-76-2*]

Special solvents
Diacetone alcohol [*123-42-2*]
N-Methylpyrrolidone [*872-50-4*]

Reactive solvents
Styrene [*100-42-5*]
Methyl methacrylate [*80-62-6*]
1,6-Hexanediol diacrylate [*13048-33-4*]

The following coating systems exist:

1) *Physically Drying Systems.* The solvent (organic solvent or water) evaporates and a solid polymer film remains on the wood surface. Typical physically drying systems are nitrocellulose (cellulose nitrate) lacquers, stains, and waterbased paints.
2) *Physicochemically Drying Curing Systems.* Here, chemical reactions occur in addition to evaporation of the organic solvent. These reactions impart improved surface properties to the coating film. The chemical reaction is either a polycondensation (with elimination of water and formaldehyde in acid-hardening coating systems) or a polyaddition reaction (e.g., in the case of polyurethane coatings).
3) *Chemically Curing Coating Systems (Polymerizing Systems).* Here, the solvent (a reactive or polyfunctional solvent such as styrene or an acrylic monomer) is copolymerized with the curable system (typically unsaturated polyester resins) to a great extent.

In addition to the type of wood or wood product and the resistance required for the expected use, because of the relatively high proportion of organic solvents contained in the coating system, the corresponding environmental regulations (national, European, or international) must also be taken into account when selecting a paint system. The first priority is the maintenance of air purity (i.e., reducing the quantity of organic solvents) regulated by national laws. Waste avoidance and disposal and storage conditions (as stipulated, e.g., by the German water management law) are also important.

Besides the nature of the coating system and the proportion of organic compounds contained, the application process and its efficiency also determine the quantity of organic solvent emitted. The choice of application system depends, however, on the shape of the workpiece to be painted. The limiting values for residual emissions from the dried or cured coating are being constantly reduced to protect the end user.

Processes for surface treatment of wood products and furniture include preparation (shaping, grinding, etc.), bleaching, bleach-staining, staining, primary coating, intermediate grinding, and application of the top coating.

2. Bleaching

The *dyes* present in wood often have low resistance to sunlight and the wood can become discolored or altered. Three types of change occur. The wood becomes lighter (e.g., jacaranda); it becomes darker (e.g., oak, macoree, Canadian cherry); or its color changes (e.g., European cherry).

In the treatment process, unstable dyes are decomposed by bleaching with oxidants (generally hydrogen peroxide with appropriate additional components) and the color shade of the

wood is then reproduced by using synthetic organic dyes. This bleaching process is carried out primarily on light-colored woods (e.g., maple, birch), various types of cherry, and American walnut. Either the whole or part of the surface is bleached. After applying the oxidizing agents, the wood must be dried at room temperature (20 – 30 °C) for 24 h. In industry the drying time is reduced to 5 – 15 min at ca. 100 – 120 °C. The residual peroxide retained after drying can give rise to discoloration in the case of polyurethane curing components (aromatic polyisocyanates). For certain workpieces, bleaching and staining are carried out simultaneously.

Table 1. Coating systems for furniture and interior decoration

Type of coating	Solvent content, %	Water content, %
Water stains		90 – 95 %
Solvent stains	95	
	70	25 – 30
	30	60 – 70
Nitrocellulose lacquer, colorless	75	
Nitrocellulose lacquer, pigmented	60	
Acid-curing coating, 2-component, colorless	56 – 60	
Acid-curing coating, 1-component, colorless	70 – 75	
PUR [a] coating, colorless	70 – 75	
PUR [a] coating, pigmented	35 – 60	
PUR [a] coating, medium solid, colorless	40 – 50	
UP [b] coating, conventional	35 (15 [c])	
UP [b] coating, UV curing	35 (15 [c])	
UP [c] roller coating, UV curing	0 – 2	
UP [b] paste coating, UV curing	0	
UP [b] spray coating, colorless	65 – 70	
UP [b] spray coating, UV curing	65 – 70	
Waterbased paint, conventionally drying	5 – 7	60 – 65
Waterbased paint, UV curing	2	58 – 60
Waterbased paint, PUR [a] 2 C [d]	9	60

[a] PUR = polyurethane;
[b] UP = unsaturated polyester;
[c] 15 % reactive solvent styrene (emitted);
[d] 2 C = two component.

3. Staining

Staining can be carried out over the whole or part of the wood's surface (to compensate for color defects in the wood or veneer). Staining changes the color of the surface but not the wood structure. The shade always becomes darker compared with bleaching, and the natural grain is enhanced.

The shade of stained wood consists of two main components: the basic color shade of the wood and that of the stain. With certain types of wood – for example, those containing tannins – additional side reactions (e.g., with tannic acid) can occur.

3.1. Stain Systems

Three stain systems exist: water stains (main solvent water), solvent stains (ca. 30 – 95 % organic solvent), and chemical stains (which are generally water thinnable).

Stains always consist of solutions of organic dyes in solvents. Micronized pigments can also be incorporated to achieve better covering of the wood surface. Reactive dyes are used in chemical stains. These dyes react with the wood components such as tannins or resin acids in coniferous woods.

Water Stains. The classical stain system is the water stain, i.e., an aqueous solution of highly lightfast organic dyes. Alkali is sometimes added to achieve better wetting of the wood pores.

Water staining is easy to carry out. It gives very attractive, even surfaces. However, water stains have certain disadvantages:

1) The wood is severely roughened by the water; i.e., wood fibers that have not been completely cut off during grinding protrude again.
2) A relatively long drying period is required.

Roughening of the wood can be avoided by first wetting, drying, and then regrinding it.

Solvent Stains. To speed up processes both in industry and in craft workshops and to avoid roughening, solvent stains were developed. Here, an organic solvent is used instead of water. The dyes, which are highly lightfast, hardly change during normal use. A variety of solvent stains exist, and many have been adapted for use in industrial plants. However, solvent stains contain up to 95 % organic solvent, all of which is emitted.

With solvent stains, equalizing effects are achieved, depending on the additives. This is

particularly important in the case of cross-grain veneers and the cross-cut edges of solid wood parts.

Chemical Stains. Chemical stains produce the color shade as a result of a reaction between stain components. Previously, only *two-component stains* were in use, but *one-component stains* developed in the 1980s are now on the market. The latter react with the wood components themselves. Coniferous wood (softwood) stains are the most well known. Here, the resin acids react with the stain dye. If normal water stains are used, a *negative stain* is formed on the coniferous wood; i.e., earlywood is rendered significantly darker by staining than latewood. This is associated with the suctional capacity of the soft earlywood. The natural appearance of coniferous wood is, however, the reverse; i.e., earlywood is lighter than latewood. To maintain the natural appearance of coniferous wood by staining, *positive stains* are used. These dye latewood significantly darker and earlywood to a much lesser degree. However, in the case of coniferous wood exact periods of application (usually 16 h) must be adhered to. Also, the surface must be brushed. Positive stains can be used with other types of wood, as well (e.g., beech, oak, and cherry). They give very even coloration of the wood surface, without producing the positive effect.

For certain pieces of furniture in which the staining of certain parts of the furniture is to be particularly pronounced (e.g., antiques), *antique or wiping stains* are used.

3.2. Application of Stains

In *craftwork*, stains are applied by using a brush or a sponge and then spread evenly over the entire surface. In *industry*, stains are applied evenly by smooth or cellular rubber rollers. This allows significant reduction in the quantity of stain applied. Distribution over the surface is effected by rapidly moving brushes that operate at an angle over the object.

Combination Staining. To fulfill environmental requirements, in the late 1980s a new type of staining has been developed – combination staining – which is intermediate between water and pure solvent staining. It involves the use of a mixture of organic dyes, water, and organic solvents that can be diluted with water

4. Coating Systems

4.1. Cellulose Nitrate Lacquers (→ Paints and Coatings, Chap. 2.2.1.)

Cellulose nitrate (CN) lacquers [nitrocellulose (NC) lacquers, nitrolacquers] belong to the large group of physically drying coating systems. They have been used in the furniture industry for decades. The lacquers consist of a solution of cellulose nitrate and appropriate plasticizers (phthalates or various resins) in an organic solvent. Nitrocellulose lacquers contain ca. 70 % organic solvent. The solid material content is limited by the cellulose nitrate because the viscosity of the lacquer increases more than proportionally with increasing cellulose nitrate content.

The application of nitrocellulose lacquers is straightforward. In industry, practically any drying time is possible. The lacquers can be applied by spraying, with rollers, and by pouring and dipping.

Many different types of CN lacquers exist. Particular surface effects – from high gloss to deep matt – can be produced easily on furniture.

Cellulose nitrate lacquers intensify the color of the wood considerably and strongly enhance its structure. *Brightener* (*natural wood effect*) *lacquers* can be produced by mixing other cellulose esters (e.g., cellulose acetate butyrate) with cellulose nitrate. Since cellulose esters are physically drying coatings, swelling and dissolving effects as a result of the subsequent action of organic solvents (e.g., esters and ketones) are unavoidable. The resistance toward organic solvents, some of them in daily use, is therefore limited. Cellulose nitrate lacquers also have a limited lightfastness. Discoloration or yellowing of cellulose nitrate lacquers occurs mainly with very light woods such as maple, birch, or ash. However, it can be improved by various photoprotective agents.

4.2. Polyurethane Coatings

Polyurethane (PUR) coatings are systems that are converted into a usable form by the addition

of hardeners (Paints and Coatings, Chap. 2.9.). Unlike urea resins and the acid-curing coatings produced from them, curing occurs here by polyaddition; i.e., no cleavage products, such as formaldehyde, are liberated during curing, not even at a later stage. The hardener and paint must be mixed in a precise ratio, which is determined by the stoichiometry of the chemical reaction. This ratio generally involves whole numbers (e.g., 5 : 1 or 10 : 1).

Polyurethane coatings consist of two components. The first is a hydroxyl-group-containing resin (or resin components) together with appropriate plasticizers, flow-control agents, and accelerators. The second reaction component (hardener) is a polyisocyanate. The building blocks of the polyisocyanates are toluene diisocyanate (TDI) or hexamethylene diisocyanate (HDI). These monomers are unsuitable for use in industry because their vapor pressures are too high. For safe handling, higher molecular mass products with lower vapor pressures are produced. These prepolymers still contain small quantities of monomers (>0.2 %). The *hydroxyl components* are polyester polyols or hydroxyl-group-containing acrylic resins. They cross-link with aliphatic isocyanates to form rapidly drying products with high lightfastness. During formulation, no water or hydroxyl-group-containing solvents (e.g., alcohols) must be present; otherwise, side reactions can occur that impair the resistance of the coating. The reduced amount of paint required and the fact that the paint system is more concentrated compared to nitrocellulose lacquers lead to lower solvent use.

At present, *medium-solid polyurethane coatings* with excellent surface properties can be produced, even for wood.

Uses. Polyurethane coatings are extremely versatile. Colorless and pigmented coating systems have been developed in all matt grades. Natural wood effects can be achieved easily. Even highly elastic coating films can be produced so that plastics (including soft plastics), which are processed together with wood (e.g., in kitchen furniture), can be coated. Polyurethane coating films have an exceptionally high resistance toward usual household chemicals as defined in DIN 68860-68861 and the corresponding EN and ISO standards. They are also unaffected by the components of wood and are often the only means of achieving a satisfactory coating when, for example, wood components interfere with other curing reactions.

Polyurethane coatings with low flammability, according to the requirements of DIN 4102, group B 1 also exist; these are particularly important for public buildings and interior furnishings for hotels, restaurants, and conference centers.

The cured coating films meet the German legal requirements for foods. The films are resistant to perspiration and saliva according to DIN 53 160. A particular feature of polyurethane coating systems is their strongly pronounced insulating and impregnating effect, which is important for precoating MDF boards.

Applying two consecutive coating films seals the wood surface so that in the case of veneered particle board, possible residual emissions of formaldehyde are reduced. These emissions can originate from the particle board itself or can be due to other processes, such as veneering with urea resins, even when E 1 particle board (→ Wood, Chap. 2.5.2.2.) is used. The maximum permissible concentration of formaldehyde emitted from wood products according to GefStoffV is 0.1 ppm. If these types of surface are coated by double application of a polyurethane paint, the formaldehyde concentration, which can increase to >0.1 ppm during veneering with urea resin-containing glues, is reduced to a quarter of the original value. This can, however, be achieved only by using E 1 board and applying special treatment to drilled holes and narrow edges.

4.3. Unsaturated Polyester Coatings

(→ Paints and Coatings, Chap. 2.8.)

Unsaturated polyester (UP) coatings are reactive systems that are purely chemically curing. Cleavage products, such as formaldehyde, are not liberated. The solvents used are polyfunctional reactive solvents; i.e., they serve to adjust processing viscosity and are partially copolymerized with the unsaturated polyester film during polymerization. Compared with other solvent-containing systems, the quantity of solvent contained is not the same as that emitted.

Classical *paraffin-containing polyester* systems, which dry conventionally, are intended for

high-gloss coatings. They are still widely used, e.g., on decorative parts for cars and small objects (e.g., clock cases) with particularly high-gloss effects. Ready-made UP systems are available in the most widely differing colors and matt grades, and are important for industrial surface treatment. Owing to the development of MDF boards that require special priming, pigmented polyester filler systems have been introduced.

Matt polyester coatings for open-pored effects are also still in use. They do contain not only styrene as the solvent, but 60 – 70 % normal organic solvents, as well. To initiate the chemical reaction in any polyester coating system the following are required: an accelerator, normally an organometallic compound (cobalt octanoate), and an organic peroxide solution as the curing agent.

Once mixed, the coating can be applied for only a limited period. Therefore, in industry, only two-component (two-pack) coating systems are generally employed. For flat surfaces (e.g., in the industrial coating of doors and parts for bedroom furniture), hardeners are applied separately either by pouring or with rollers.

Radiation Curing. The chemical reaction can also be initiated *by IR or UV radiation*. Unsaturated polyester resins or special acrylate-modified UP resins can be cured by UV radiation. When using UV-hardening systems, a photoinitiator must always be added. Accelerators based on organometallic compounds and organic peroxides need not be used. The reactivity of the coating system and the application equipment determine to a large extent the number and electrical power of UV lamps required.

Since the hardening components are separated from the actual paint system, the potlife of the system is prolonged and the amounts of special waste are reduced because cured coating residues are not produced.

Acrylate-modified polyester resins are significantly more reactive than unsaturated polyester resins and allow higher rates of feed, fewer UV lamps, and thus less energy input.

Developments of paint raw materials have reached a high level so that a large number of coating systems applied with rollers and spatulas are virtually solvent free. Novel *UV-curing water-thinnable* materials are also in use. They are not comparable to conventional water-thinnable systems. The new systems are generally emulsions with a maximum organic solvent content of 2 – 2.5 %; the main solvent is water. In processing these systems, milling, grinding, and priming must be performed especially carefully. Since water is the main solvent, longer drying times are necessary, generally 5 – 10 min on a flat bed dryer, depending on the quantity. If shaped articles are to be coated, depending on the shape, evaporation times of 15 – 25 min are necessary with a stepwise rise in temperature. If the water is not evaporated entirely, visible white stripes appear immediately after UV curing of the paint, which cannot be removed. Because of the increased use of UV-hardening polyester systems, completely new technologies have been developed in many areas (e.g., the parquet and door industries). An example of a production line for UV-curing coating of smooth, flat parts is given in Figure 1, the quantities of coating applied are listed in Table 2. This technique satisfies environmental requirements (protection of raw material resources) because of the small quantities of coating required. These are usually 10 – 20 g in priming and 10 – 20 g in the top coating.

Table 2. Example of and quantities applied in a production line for roller coating of smooth flat workpieces using a UV curing paint ∗

Type of process	Applied quantity of coating, g/m^2	Quantity of solvent, g/m^2
Priming (water-thinnable, sometimes colored, solvent 2 %)	20	1
Spray drying		
Staining (combination stain, solvent 30 %)	20	6
Spray drying UV roller priming (solvent 2 % max.)	15	1
UV curing zone		
Grinding		
Intermediate staining (only when complete UV curing is used, solvent 90 %)	8	7.2
Spray drying		
UP upper coating (solvent ca. 5 %)	10	0.5
Total quantity applied	93	16.7

∗ These coatings can be produced as complete UV curing coatings. Alternatively, the coating can be applied by pouring or spraying using other systems (e.g., NC or PUR coatings), after priming and grinding.

4.4. Waterbased Paints (→ Paints and Coatings, Chap. 3.3.)

Waterbased paints were developed in the 1950s to replace organic paint solvents with water, which is noncombustible and nontoxic. Waterbased paints for the furniture industry are based on proven coating raw materials (acrylate dispersions).

These paint systems have three advantages: (1) the main solvent is water; (2) no environmentally polluting cleavage products are liberated during drying; and (3) the fastness of the coating is excellent.

For certain types of wood and certain color shades, photoprotective agents must be added, particularly for light wood (e.g., special types of maple) and for light stains.

For technical reasons, waterbased paints still contain ca. 5 – 7 % organic solvents. Their constitution is, however, completely different from that of solventborne products. In addition, waterbased paints based on polyurethane, polyurethane – acrylate, or UV-curing coating systems exist.

In *conventionally drying* waterbased paint systems, film formation occurs after evaporation of the water in such a way that the binder components bond to one another and become fixed, thus forming a largely water-insoluble film. For film formation, however, the temperature must not fall below a certain value – the minimum film-forming temperature (16 – 18 °C). Waterborne paint can be applied only at 18 °C, the materials to be coated must be at this temperature.

Wood is swelled by water, and protruding wood fibers cause roughening of the surface. The corresponding preliminary processes must be adapted to compensate for this. A normal water stain can be used only when suitable additives are added. The color intensification achievable with polyurethane and nitrocellulose coatings cannot be obtained with waterborne paints in the case of dark or very bright color shades. It can be achieved, however, with bright mahogany shades by coloring the waterbased paint. When the same coating quantity is applied, waterbased paints have a significantly higher filling power than other paints with virtually the same solid material content. For use in spraying, machines equipped with warming devices have proved particularly useful. Practically no odor is perceptible when the objects are used to furnish existing houses or workplaces. The same applies to parquet coatings. Like polyurethane coatings, waterbased paints are highly insulating, so that the formaldehyde emitted from veneered particle board is far below the equilibrium concentration. A prerequisite is, however, the use of E 1 board and special treatment of drilled holes and narrow edges.

A novel development is the production of *UV-curing water-thinnable* coatings (see Section 4.3). Here, particular precautions must be taken during predrying before actual UV curing.

More recent developments start with water-thinnable *polyurethane coating system*. Here, mixing with the polyisocyanate component, which can have varying viscosities compared to the waterborne paint, must be carried out carefully. Two-component metering devices are recommended, since the potlife is between 2 and 3 h at normal temperature.

5. Paint Application

Although the emission of organic solvents during hardening of a coating depends on the coating materials used (solvent content and quantity applied per square meter), the application process and its efficiency are extremely important. The type of application system used is determined by the production program and the shape and dimensions of the workpiece to be coated. It is also influenced by downstream costs involving, for example, waste production and disposal and, particularly, the overall cost per square meter of coating. Emissions and waste production

are controlled by national and international regulations and must be continuously adapted to the current state of the art. With highly efficient application systems [e.g., dipping, pouring, or rollers (efficiencies 95 – 98 %)], virtually no room exists for improvement.

In *spray systems*, losses due to overspraying are unavoidable and depend on the shape of the coated workpiece. These losses can be minimized by further development of spraying machines with recycling devices, e.g., recovery from the conveyor belt, which allows a significant reduction in the quantity of coating used and thus the cost per square meter at a relatively low investment cost. These recycling devices can be incorporated into existing spray systems. For the use of spraying machines to be reasonably economical, a certain number of workpieces must be coated both simultaneously and subsequently. The amount applied by a spraying machine can be reduced through the use of several spray guns.

6. Paint Curing Methods

After the coating material is applied, the paint must be transformed from the liquid to the solid state as quickly as possible in the absence of dust. Drying must be environmentally friendly, energy saving, and low cost. In industry, paints cannot be dried at room temperature because this is time-consuming and requires too much space. All drying and hardening plants utilize the physical principle that the vapor pressure of a solvent increases with temperature and drying time decreases. At the same time, chemical reactions are accelerated, and curing times thus shortened. The solvent must be removed by suitable means, generally by passage of air, the quantity of which varies with the quantity of solvent. The upper and lower explosion limits of the solvent – air mixtures must be taken into account.

6.1. Heat-Drying Systems

Drying is performed with circulating heat carriers, usually a hot-air stream. Heat-drying systems include:

1) Multi-shelved dryers, aerated left and crosswise
2) Flat track, aerated by a countercurrent
3) Nozzle drying channels with special nozzle systems and high air velocities
4) Tower dryers with different temperature zones, which can be regulated individually

All CN lacquers, PUR coatings, solvent stains, water stains, conventional waterbased paints, and UP coatings can be dried or cured with these heat-drying systems. The construction and mechanical components of these types of drying systems are rather simple. However, a relatively high quantity of heat is required because the air must be heated and then passed over the coated workpiece. This air, together with the evaporated solvents, is generally emitted directly into the atmosphere, particularly in the case of old dryers. Ca. 95 % of the heat energy supplied is thus lost. Simple plants consist of an application device (manually operated spray zone, automatic spraying machine, or pouring machine, a predrying zone, and an evaporation zone). After application, the coated parts are placed in a tray truck and predried in front of an evaporation wall. Part of the solvent is thus emitted into the workplace. The predrying zone is generally followed by temperature-regulated evaporation zones where the temperature rises continuously from 30 to 50 °C.

Drying and hardening by hot air (convection drying) has a relatively poor heat balance. The hot air naturally heats the coated workpiece. A large proportion of the heat energy is used to heat the drying chamber and drying devices, at least in the initial phase. No UV-hardening materials or materials that need to be hardened by electron beams can be cured in convection-drying plants. Steam, hot water, and – at higher temperature – oil are used as the heat medium in these plants.

6.2. Radiation-Curing Systems

The radiation-curing systems IR, UV, and electron-beam curing (EBC) are much more effective. The curing reaction can be accelerated considerably by energy-rich radiation. However, not every type of radiation is suitable for every type of binder. In all radiation-curing systems, energy is not transferred by the ambient air; rather, it interacts directly with the coating

layer, resulting in much more rapid energy transfer (with convection drying the power transfer is between 2 and 5 kW/m^2; with radiation, between 10 and 50 kW/m^2). No startup times, as with boiler houses or heat production devices, are required.

6.2.1. IR Irradiation

Irradiation with IR provides an effective method for accelerated curing. Short- (1.5 – 1.6 μm), medium- (2.5 – 3.0 μm), and long-wavelength (3.5 – 6.0 μm) radiation can be used.

Basically, three physical processes can occur during IR drying: adsorption, reflection, and transmission of radiation. The most efficient process is adsorption, which depends on the thickness of the coating layer and its components. Here, the radiation is converted directly into heat in the coating layer. Medium-wavelength radiation has proved most suitable for wood coating. Generally, twin radiation scources with vapor-deposited reflectors in a quartz casing are used. The radiation sources can be readily built in existing plants. The sources are robust and do not contain any sensitive mechanical components. The physicochemically drying and chemically hardening systems are suited to curing by IR radiation.

6.2.2. UV Curing

UV curing requires special coating systems (see Section 4.3; → Paints and Coatings, Chap. 3.7.). The radiation sources are basically high-pressure mercury lamps with a power output of 80 – 100 W per centimeter arc length. These lamps emit their energy in the form of impulses at a frequency of 100 Hz. Some lamps have been developed more recently with a much higher pulse rate (>100 Hz).

During UV curing, ozone is always produced underneath the radiation source. It is generally removed by means of ventilators that cool the source. UV radiation is generally used for curing stain and paste materials involving colorless and pigmented systems. For pigmented systems the radiation source must be doped accordingly, because not every pigment or color shade can be hardened in the same way and at the same time. The use of UV-curing systems to coat flat workpieces is relatively simple. However, by means of special plants and special arrangement of the radiation source, solid objects and chair frames can now also be irradiated.

6.2.3. Electron-Beam Curing

Unlike UV or IR radiation, which consist of electromagnetic waves, electron beams are not reflected by pigments. Highly accelerated electrons penetrate materials that are impermeable to light, so the system is equally suitable for clear varnishes and pigmented coatings. Electron-beam curing has the shortest drying times. The cost of the plant is relatively high, but energy costs are very low. Special coatings based on unsaturated acrylates must be used. Curing must be carried out in the absence of atmospheric oxygen, i.e., in an inert gas atmosphere (nitrogen). The secondary radiation (X-rays) produced during electron-beam curing requires complex radiation shielding.

1. Introduction

Today, wool accounts for only ca. 3 wt % of world textile-fiber production. However, if the value added by dyeing and printing is included, the share in monetary terms is considerably higher. The importance of wool is due to its unique physiological properties as a clothing material and the wide range of techniques for converting it into textiles, including felts and finishing processes.

Some important methods and discoveries in modern biological sciences had their origins in wool research (partition and paper chromatography, the structure of α- and β-keratin, intermediate filaments).

The production of wool and woolen textiles and the trade in these commodities have played an important role in political and economic history.

1.1. Definition

The natural fiber wool, like other types of fine and coarse animal hair and also silks (→ Silk), is an animal fiber [54], and although the term "wool" can be used in conjunction with the names of various animals, e.g., "angora wool", it is here understood to include only the hair of the various breeds of domesticated sheep (*Ovis aries*).

1.2. Historical Aspects [55–57]

The wool of the sheep was the first textile raw material used by humans for clothing purposes. The development of clothing began when people first dressed themselves in the skins of mammals. Felts, which are more easily shaped, were produced later from hairs plucked or cut from the animal (→ Felts). The development of spinning and weaving to produce fabrics was a still later development.

The first country to process and trade in wool was Babylon (Babylonia = land of wool). The oldest known wool fabrics, dating from the second half of the second millennium B.C., were found in Danish tree coffins.

Sheep rearing reached a high point in the Middle Ages and the Renaissance. The merino sheep, bred in Spain, produced wool of very fine quality, and in the late 1700s Saxon merinos were exported via England and South Africa to Australia, where the climate proved to be very favorable for rearing this breed.

1.3. Biology

Wool fibers and other animal hairs, including human hair, are formed in follicles – sheath-like formations of the epidermis, at the base of which are papillae of mesodermal cells (Fig. 1).

Follicles are dynamic organs in which various processes occur simultaneously: cell division, cell differentiation, upward movement of the keratinocytes, biosynthesis of wool proteins as gene products, self-assembly of the proteins to form supramolecular structures, and finally keratinization (cornification) by formation of cross-linked disulfide and isodipeptide bridges. At the same time, cells of the inner and outer root sheath are catabolized [58].

The various stages of development of the growing wool fiber in the follicle can be divided into six zones (Fig. 1). In the upper part of Zone 1, fine keratin intermediate filaments (KIF) and trichohyalin granules are already forming. Between Zones 1 and 2, filaments aggregate to form macrofibrils, in which keratin-associated proteins (KAP) are deposited. In Zone 2, amorphous protein aggregates, ca. 30 nm in diameter, form in the fiber cuticle cells. By the end of Zone 2 the cuticle cells are hardened, while the final keratinization of the entire wool fiber occurs in Zone 3.

1.4. Chemical Composition [27, 31]

The protein fiber wool consists of carbon, hydrogen, oxygen, nitrogen, and sulfur. The elemental analysis of wool (free of water) is as follows:

Carbon	50.5 wt %
Hydrogen	6.8 wt %
Oxygen	22.0 wt %
Nitrogen	16.5 wt %
Sulfur	3.7 wt %
Ash	0.5 wt %

Except for the sulfur content, this composition is typical for all proteins. The high sulfur

content is due to the high content of cystine, a double amino acid containing two sulfur atoms in a disulfide bond:

$$HOOCCH(NH_2)CH_2S-SCH_2CH(NH_2)COOH$$

The ash contains potassium, sodium, calcium, aluminum, iron, silicon, sulfate, carbonate, phosphorus pentoxide, and chloride. Water-free wool consists mainly (ca. 97 %) of wool proteins, the remainder being made up of ca. 2 % structural lipids (Fig. 2) [59–62], ca. 1 % mineral salts, nucleic acids [63, 64], and carbohydrates.

Industrially scoured wool has only small residual amounts of wool grease (ca. 0.5 %). The structural lipids, in contrast, are components of the cell membrane complex which binds together the cuticle and cortex cells.

A characteristic of the structural lipids of the cuticle is the presence of a covalently bound branched-chain C_{21} fatty acid 18-methyleicosanoic acid [65–67].

Total hydrolysis of the peptide bonds in wool proteins yields 24 amino acids. The data given in Table 1 were obtained by combining data from acidic and from enzymatic hydrolyses of wool.

The amino acids are classified in five groups: "acidic" amino acids, "basic" amino acids, amino acids with hydroxyl groups, sulfur-containing amino acids, and amino acids with no reactive groups in the side chain. The total amount of amino acids with reactive side chain groups is 5395 µmol/g, and of amino acids without reactive side chain groups 3450 µmol/g. The sum of these two figures, after subtraction of the concentration of *C*-terminal amino acids (10 µmol/g), gives a figure of 8835 µmol/g for the concentration of peptide groups in the peptide chains of wool.

Like all proteins, wool contains both cationic and anionic groups, and is therefore amphoteric. The cationic character is due to the protonated side chains of arginine, lysine, and histidine, and to the small number of free amino groups at the ends of the peptide chains. The amino groups of lysine, histidine, the amino end groups, and the thiol groups of cysteine are important sites for the covalent attachment of reactive dyes [68]. Anionic groups are present as dissociated side chains of aspartic and glutamic acids and as carboxyl end groups.

The side chains, which in wool account for a considerable proportion (50 %) of the protein material, interact with each other, thereby stabilizing the peptide by forming links between the chains and rings within a chain:

This structural formula is a schematic representation of five such links between segments of two hypothetical peptide chains. From the top downwards it shows interactions between phenyl rings (for the role of aromatic rings as hydrogen bond acceptors see [69]), hydrogen bonds between an asparagine residue and a serine residue, a salt bridge between an arginine residue and a glutamic acid residue [70], a disulfide bridge between two cysteine residues, and an isodipeptide bridge between glutamic acid and lysine [71, 72].

The disulfide bridge plays an important part in stabilizing the wool fiber, leading in particular to its relatively high wet strength, moderate swelling, and insolubility. A second covalent bridge is provided by the isodipeptide N_ε-(γ-glutamyl)lysine, which provides an additional stabilizing effect in the cornified cell envelopes of the cortex and cuticle.

The so-called salt bridge is due to the electrostatic interaction between cationic and anionic side-chain groups. Hydrogen bonds are formed in proteins between

$>NH$ and $-\overset{|}{\underset{|}{C}}-OH$

Figure 2. Structural lipids

as donors and

as acceptors, especially in the helical rod domains of the keratin filaments.

Hydrophobic effects stabilize the aggregation of nonpolar side chains, so reducing the area of the interface with water.

The three-dimensional structure of the wool proteins is stabilized both by the hydrophobic effect and by a wide variety of electrostatic interactions between amino acid constituents [73].

Eight *N*-terminal amino acids have been analyzed by means of 2,4-dinitrofluorobenzene: cystine, glycine, threonine, valine, alanine, serine, and glutamic and aspartic acids. Other *N*-terminal amino acids are present in *N*-acetylated form. Thus, the acid hydrolysis of wool liberates 50 µmol/g acetic acid [74].

S-Carboxymethylated soluble wool proteins can be obtained by exhaustive mercaptolysis and carboxymethylation of the resulting SH groups [75–77].

The dissolved *S*-carboxymethylated wool proteins can be separated into the main groups listed in Table 2, and these fractions can be separated into definite proteins, some of which have been sequenced [78]. In two-dimensional polyacrylamide gel electrophoresis [79], the proteins are first separated according to charge, and, in the second dimension, in the presence of sodium dodecylsulfate (SDS), according to molecular mass (Fig. 3). The heterogeneity of this class of proteins can thus be demonstrated by a relatively simple analytical process. The keratins are well separated from the sulfur-rich proteins be-

Table 1. Amino acid composition of fine merino wool ∗ [49]

Group	Name	Side chain	Concentration, μmol/g
"Acidic" amino acids and their ω-amides	aspartic acid	$-CH_2-COOH$	200
	glutamic acid	$-(CH_2)_2-COOH$	600
	asparagine	$-CH_2-CONH_2$	360
	glutamine	$-(CH_2)_2-CONH_2$	450
"Basic amino acids and tryptophan	arginine	$-(CH_2)_3-NHC(=NH)-NH_2$	600
	lysine	$-(CH_2)_4-NH_2$	250
	histidine		80
	tryptophan		40
Amino acids with hydroxyl groups in the side chain	serine	$-CH_2-OH$	900
	threonine	$-CH(CH_3)-OH$	570
	tyrosine		350
Sulfur-containing amino acids	cysteine	$-CH_2-SH$	10
	thiocysteine	$-CH_2-S-SH$	5
	cysteic acid	$-CH_2-SO_3H$	10
	cystine	$-CH_2-S-S-CH_2-$	460
	lanthionine	$-CH_2-S-CH_2-$	5
	methionine	$-(CH_2)_2-S-CH_3$	50
Amino acids without reactive groups in the side chain	glycine	$-H$	760
	alanine	$-CH_3$	470
	valine	$-CH(CH_3)_2$	490
	proline		520
	leucine	$-CH_2-CH(CH_3)_2$	680
	isoleucine	$-CH(CH_3)-CH_2-CH_3$	270
	phenylalanine		260

cause of their high molecular mass, and the high glycine – tyrosine proteins are nearly at the front of the SDS dimension because their molecular mass is very low. Some of the heterogeneity of the keratins is caused by phosphorylation [80].

The keratins in wool come from the microfibrils, which together with some other protein filaments are classified as intermediate filaments [81–84]. Intermediate filaments form an important filamentary system in the cytoplasm of higher eukaryotic cells. They have a diameter of 8 – 10 nm, and are thus larger than actin filaments and smaller than the microtubuli [41] of the cell.

2. Structure

2.1. Morphology [85–89]

Wool fibers consist of two cell types: cuticle and cortex cells. In coarse fibers, there is also a central medulla (Fig. 4).

The cuticle [87] consists of plate-shaped cells ("scales") that overlap longitudinally and

Figure 3. Two-dimensional polyacrylamide gel electrophoretic separation of wool proteins [79].
The proteins were extracted from merino wool and subjected to electrophoresis at pH 8.9 in one direction and in the presence of SDS in the other.
LS = low sulfur; HS = high sulfur; UHS = ultrahigh sulfur; HGT = high glycine – tyrosine

peripherally, with the 1 µm thick edges of the scales pointing in the direction of the tip of the fiber. Each cuticle cell consists of four layers with different cystine and isodipeptide contents: epicuticle, a-layer, exocuticle, and endocuticle. Between overlapping cuticle cells is the cell membrane complex. The epicuticle consists of proteins and lipids, including covalently bound 18-methyleicosanoic acid, (Fig. 2).

The cortex consists of spindle-shaped interdigitated cells [88]. These consist of ortho, para, and more rarely meso cells, all differing in their cystine content and staining behavior with silver salts. A cortex cell of wool contains around 5 – 8 macrofibrils with a diameter of 300 nm at their widest point. Between the macrofibrils are cytoplasmic and nuclear remnants of the keratinocytes. This intermacrofibrillar material swells in water more than the macrofibrils. A macrofibril is a bundle of 500 – 800 keratin intermediate filaments (microfibrils). Keratin-associated proteins (KAP) are intercalated, enveloping individual microfibrils and their aggregates. An individual microfibril consists of protofibrils, which in turn consist of protofilaments (Fig. 5) [89].

Table 2. Proteins of the wool fiber [78]

Type of protein	Number of proteins	Range of molecular mass, kDa
Keratins		
Acidic keratins (Type I)	4	40 – 50
Basic keratins (Type II)	4	56
Keratin associated proteins (KAP)		
High-sulfur proteins	80 – 100	11
		16
		19
		23
Ultrahigh-sulfur proteins		16
High glycine – tyrosine proteins (Type I)	10	6 – 9
High glycine – tyrosine proteins (Type II)	5	6 – 9

The medulla in coarser wool fibers consists of hollow cells with a skeleton of amorphous proteins and fine filaments.

The natural color of brown wool is caused by pigment granula of black to brown eumelanin and yellow to red pheomelanin.

2.2. α- and β-Keratin

The microfibrils are partly crystalline, and on X-ray structural analysis give reflections on the meridian (0.51 nm) and equator (0.98 nm), as well as many long-period reflections on the meridian and some on the equator. Astbury [90] designates the modification that results in this fiber diagram (Fig. 6 A) as α-keratin. Wool that has been stretched by ca. 50 % in water and then steamed gives a new fiber diagram with a meridian reflection at 0.34 nm and equatorial reflections at 0.465 nm and 0.98 nm. This X-ray diffraction pattern is due to the modification known as β-keratin (Fig. 6 B). A new interpretation for the $\alpha \rightarrow \beta$ transition is given by CAO [96] and Kreplak et al. [97].

In α-keratin [91], the peptide chains are twisted like a right-handed screw (α-helix, Fig. 7). The stability of the α-helix is due to intramolecular hydrogen bonds between the >C=O groups of the peptide bonds and adja-

Figure 5. Schematic representation of the three distinct levels of fibrillar organization in keratin filament assembly and architecture [89].
I) The 2 nm protofilament consists of two coiled-coil keratin polypeptides, presumably one acidic (white) and one basic (black) species; II) The 4.5 nm protofibril may be a six-stranded subunit composed of three 2 nm protofilaments (shown on left), or, alternatively, may be an eight-stranded subunit formed by the lateral aggregation of two four-stranded 3 nm protofilament intermediates (shown on right); III) The 10 nm filament may comprise four (left) or three (right) protofibrils, depending upon protofibril substructure. The number of protofibrils (four or three) per 10 nm filament is not unique but just represents one possible polymorphic form.

cent >N−H groups of amino acid units located on the next turn of the α-helix and intrahelical salt linkages.

Figure 7. α-Helix structure of α-keratin [91]

The α-helix contains 18 amino acid units in five turns, i.e., 3.6 amino acid units per turn. To give the distance between successive turns of the helix that leads to the observed meridian reflection (0.51 nm), the helical chain must itself be slightly coiled (superhelix, coiled coil). Two superhelices combine to form a left-handed, two-stranded, rope-like assembly in which the superhelices are arranged such that the hydrophobic side chains on the outside of the helix interlink to form a stable "buttonhole" structure. These dimers are the actual physical structural elements of the intermediate filaments (microfibrils), and can be termed "molecular twins."

In the β-keratin structure [92], the peptide chains are considerably stretched, as in silk fibroin (→ Silk, Chap. 2.1.). The chains form so-called pleated sheet structures (Fig. 8). The sheet is formed by cross-linking of the chains by hydrogen bonds between peptide groups of opposing chains. The sheet is folded at the −CHR groups of the chains to such an extent that the meridian reflection of the β-keratin X-ray diffraction pattern at 0.34 nm corresponds with the geometry of the model. The phenomenon of the $\alpha \rightarrow \beta$ transformation has been applied in the new developed OPTIM technology (see Section 5.4).

Figure 8. Pleated sheet structure of β-keratin [92]

2.3. Two-Phase Model

The complex morphological and molecular structure of wool (Fig. 4) echoes the construction principle of all biological composite structures and many man-made materials, combining components with different properties in one material so as to maximize suitability for its purpose. Table 3 shows the stepwise differentiation of the morphological structure of the wool fiber into the most important two-phase structures.

With regard to elastic properties, the essential difference between the components is in their degree of order. If only the α-helical central rod-like domains in the microfibrils (intermediate filaments) are regarded as microcrystalline, the crystalline phase accounts for 30 % of the fiber [93]. The other components make up the non-crystalline phase, which includes the cuticle, the cell membrane complex, the intermacrofibrillar matrix, the intermicrofibrillar matrix, and 40 % of the microfibrils, i.e., the nonhelical ends of the keratin molecules or of the dimers.

On stretching the fiber in the linear-viscoelastic region ($\varepsilon < 0.8$ %), the behavior of the crystalline phase (hx) is linearly elastic and

Table 3. Morphology of wool as a combination of two-component structures (see also Fig.)

Composite system	Type ∗	Component 1	Component 2
Wool fiber	r/c	cuticle	cortex
Cortex	f/m	cortex cell	cell membrane complex
Cortex cell	f/m	macrofibrils	intermacrofibrillar matrix
Macrofibril	f/m	microfibrils	intermicrofibrillar matrix

∗ r/c = ring/core structure; f/m = filament in matrix

that of the noncrystalline matrix (nc) is linearly viscoelastic.

The modulus of elasticity of the helices is [94]

$$E_{\mathrm{hx}} = 7.8 - 9.6\,\mathrm{GPa}$$

This value is remarkably close to the modulus of elasticity of crystalline ice, which is also stabilized by hydrogen bonds (ice I, 0 °C: $E = 10$ GPa). This fact emphasizes the ideal arrangement and cooperation of the short α-helical segments in the microfibrillar crystal. The time-dependent modulus of elasticity of the dry (d) and wet (w) noncrystalline phase (nc) are calculated to be

$$E^{\mathrm{d}}_{\mathrm{nc}} = 6.1 - 6.6\,\mathrm{GPa};\quad E^{\mathrm{w}}_{\mathrm{nc}} = 0.5\,\mathrm{GPa}$$
$$E^{\mathrm{d}}_{\mathrm{nc}}/E^{\mathrm{w}}_{\mathrm{nc}} \approx 13$$

The ratio of the moduli of elasticity of the noncrystalline phase is in good agreement with the ratio of the corresponding torsion moduli ($G^{\mathrm{d}}/G^{\mathrm{w}} = 10$) [94]. In a filament – matrix composite, the torsion behavior is mainly a property of the matrix. The small difference between the values for the viscoelastic modulus of the noncrystalline phase in the dry state and the modulus of elasticity of the helical filaments is due to the fact that both components are stabilized mainly by strong hydrogen bonds which are broken under the influence of water in the noncrystalline phase, while they continue to exist in the crystalline region.

For small amounts of longitudinal strain in the linear-viscoelastic region, the relaxation behavior of a wool fiber shows no fine structure ascribable to individual morphological components. This fact can be explained by the low contents of individual components and their chemical and structural similarity. For small deformations, all noncrystalline components behave as constituents of a homogeneous mixture, whereby the effect of each component is proportional to its volume fraction. The elastomechanical behavior is satisfactorily represented by the simple Feughelman two-phase model [95]. The elastic and viscoelastic properties of the fiber largely determine the crease resistance, dimensional stability, drape, and handle of a fabric.

3. Properties [2,6,17,48]

(See also → Fibers, 1. Survey; → Fibers, 6. Testing and Analysis)

3.1. Physical and Mechanical Properties [17]

Wool fibers with no medulla have a density of 1.31 g/cm^3 at 25 °C and 65 % relative humidity. The mean fiber diameter varies between 16 and 40 µm and the mean fiber length between 2.5 and 25 cm, depending on type and origin.

Figure 9. Moisture absorption of wool as a function of relative atmospheric humidity at 25 °C [98]

Water Absorption. Wool is hygroscopic, and the amount of water taken up depends on the relative humidity of the air, temperature, and the history of the wool (Fig. 9) [98, 114, 115]. The adsorption and desorption curves exhibit hysteresis. At average relative humidities, the

difference between the two curves is ca. 2 %. As with all textile fibers, the moisture uptake of wool is accompanied by liberation of heat.

Although wool is hygroscopic, its surface is hydrophobic towards liquid water and is therefore difficult to wet. This apparently contradictory behavior, which is an important factor in the physiological effects of wool as a clothing material, is due to the fact that the interior of the fiber absorbs water vapor, whereas liquid water is repelled by the hydrophobic outer surface of the cuticle.

Water absorption results in swelling, whereby wool shows considerable swelling anisotropy, i.e., longitudinal and radial swelling are different (Fig. 10) [10].

Figure 10. Effect of moisture absorption on swelling and moduli [10]
a) Length swelling; b) Radial swelling; c) Torsional modulus; d) Extensional modulus

An increase in the amount of absorbed moisture from 0 % to 33 % leads to a longitudinal swelling of ca. 2 % and a radial swelling of 16 %. The extent of swelling depends on the pH and composition of the swelling medium.

The degree of fiber swelling is least at the isoionic point (pH 4.9), where there is no excess of ionic groups. Above and below this point, the number of stabilizing salt bridges decreases, and the wool carries excess negative or positive charges which cause electrostatic repulsion of the peptide chains, thereby increasing the swelling [99]. Many physical and mechanical properties of wool depend on its moisture content. Thus, for example, dry undamaged wool has an ultimate tensile strength of ca. 150 – 200 N/mm^2 in its initial state and a wet ultimate tensile strength of only 70 – 80 % of this value. Whereas the tensile strength of wool decreases with increasing moisture content, the fracture strain increases. In the dry state, it is 35 – 55 %, and in the wet state 40 – 60 %.

Stress – Strain Behavior. Figure 11 shows the stress – strain behavior of a wool fiber in standard atmosphere of 65 % relative humidity at 20 °C compared with that in water at 20 °C. The stress – strain curve can be divided into three regions which are affected to different extents by increasing humidity. After decrimping (not shown in Fig. 11), the tension in the fiber increases very rapidly and almost linearly up to a strain of 1 – 2 %. This so-called initial region (A – B) is often incorrectly referred to as the "Hookean region". Above this, the elongation increases rapidly for small increases in stress. This section of the curve (B – C) is known as the yield region. Point C lies between 25 and 30 % elongation. The third region of the stress – strain curve is known as the post-yield region (C – D), and is terminated by rupture of the fiber (D). In this section of the curve, the increase in tension that accompanies a given increase in elongation is larger.

The three characteristic regions of the stress – strain curve are very distinct in water at 20 °C, and the transitions at points B and C are sharp. The slopes in the initial, yield, and post-yield regions are in the approximate ratio 100 : 1 : 10. It has been shown that distinct domains of the keratin filaments undergo the $\alpha \rightarrow \beta$ transformation in the three regions [116].

Noteworthy is that when the wool fiber is stretched in water to point C at room temperature, i.e., by ca. 30 %, there is complete reversibility of mechanical properties if the time in the stretched state does not exceed ca. 1 h. If the fiber is then relaxed and kept in water at room temperature overnight or at ca. 50 °C for 1 h, not only does the fiber return to its original length, but, on repeating the test, gives the same stress – strain curve as in the first cycle.

This high degree of reversibility is not exhibited by any other fiber.

Figure 11. Tensile stress – strain diagrams

In addition to this simple tensile test, tensile elasticity testing can provide further information about the behavior of the fiber. Here the fibers are stressed several times between constant elongation limits or constant tension limits. The test enables the permanent elongation and the elastic elongation to be determined. In this way, the elastic behavior of fibers over the whole range of elongation up to the point of rupture can be determined.

Glass-Transition Temperature. Knowledge of the glass transition temperature T_g of wool [100] as a function of water content is of central importance for understanding its viscoelastic fiber properties, especially under the varying conditions of moisture content and temperature that can exist during the manufacture and wearing of woolen fabrics, and also for an understanding of the aging and tempering processes of these fabrics.

A simple equation due to Fox [101] represents the relationship between the glass-transition temperature of wool and its water content:

$$\frac{1}{T_g} = \frac{w_1}{T_{g1}} + \frac{w_2}{T_{g2}}$$

The mass fraction of each component is represented by w, the indices 1 and 2 denoting dry wool and pure water respectively. By replacing w_1 by (1-w_2), the Fox equation becomes

$$\frac{1}{T_g} = w_2 \left[\frac{1}{T_{g2}} - \frac{1}{T_{g1}} \right] + \frac{1}{T_{g1}}$$

If the reciprocal of the glass-transition temperature of the wool – water system is plotted against the mass fraction of water, a straight line is obtained, confirming the validity of the Fox equation [101]. The glass-transition temperatures of the pure components can be calculated from the slope and the intersection of this line with the axis. The time-dependent recovery of wool fibers after a fixed torsional deformation as a function of temperature and water content has been measured. For dry wool, this gave T_{g_1} = 447 K (174 °C), and for water T_{g_2} = 125 K (−148 °C) [100]. Figure 12 shows the glass-transition temperature of wool as a function of water content in the fiber.

Figure 12. Glass-transition temperature of wool as a function of mass fraction of water in the fiber [100]

The temperature dependence of the physical properties of wool – water systems has been investigated by many authors using a variety of

methods. Wool in water has a T_g of $-5\,°C$, significantly below room temperature. Thus, water in wool eliminates aging and tempering effects because the thermal history of the wool is erased when T_g is exceeded, in analogy with the behavior of other glassy polymers.

3.2. Chemical Reactivity [5,13,27,31]

Dry Heat. Dry wool free of chemicals is stable for hours at 150 °C. Short heating periods, e.g., 185 °C for 30 s, produce tolerable changes in the fibers.

Moist Heat. Depending on the temperature, pH of the liquor, and duration of heating, heating with water can lead to degradation of wool. Heating with water at 130 – 140 °C leads to the disappearance of the α-keratin X-ray diffraction pattern with chemical decomposition. Wool is most stable near the isoionic point (pH 4.9), but chemical degradation occurs even below 100 °C. The cysteine in the wool proteins is decomposed first, liberating hydrogen sulfide which then attacks the cystine in the wool and accelerates the decomposition autocatalytically [102]. This is the cysteine – cystine self-degradation and self-cross-linking mechanism (thiol – disulfide degradation reaction).

B = amino groups of histidine or lysine residues and main-chain end groups.

First step: self-degradation of cysteine residues by heat-induced β-elimination. Formation of dehydroalanine residues and hydrogen sulfide.

Second step: self-degradation of cystine residues by reduction of disulfide bonds with hydrogen sulfide. Formation of *S*-thiocysteine and cysteine residues.

Third step: Self-cross-linking by reaction of cysteine and lysine residues with dehydroalanine residues. Formation of lanthionine and lysinoalanine cross-links.

Beside cross-links based on sulfur, also further cross-links are formed in wool during heat exposure, e.g., linking via formation of dityrosine [117,118].

Acid Degradation. Mineral acids can degrade wool proteins to an extent that depends on pH, temperature, duration of reaction, and the presence of salts and surfactants. Sensitive sites in the wool proteins include the side chains of asparagine and glutamine, from which ammonia is released, and the peptide bonds formed by serine, threonine, cysteine, aspartic and glutamic acids, and tryptophan. The liquors from acid-degraded wool contain ammonium salts, free amino acids, and peptides ("wool gelatins") [103,104]. The hydrolysis of peptide bonds leads to weight losses and the liberation of end groups in the wool proteins. Carbonizing by heating wool impregnated with sulfuric acid produces an N → O peptidyl shift in the serine and threonine units of the peptide chain. The reaction is reversible if the acid is removed after the process, but if the wool is stored in moist air in the *O*-peptidyl form, the peptide chain is slowly and irreversibly hydrolyzed:

Degradation by Alkali. Wool is sensitive to alkali. In alkaline solution, the alkali binds to

the wool proteins with swelling and simultaneous degradation. Even at low hydroxide concentrations, the reversible binding is accompanied by fiber damage. The alkali binds to the wool so firmly that it cannot be completely removed by washing with water alone. The alkali salts of the wool proteins must first be decomposed by reaction with stronger acids. Wool containing alkali residues undergoes decomposition on heating in a stream of dry air, the most important degradation reactions being the decomposition of cysteine and cystine. Alkalis hydrolyze the primary carbonamide bonds of asparagine and glutamine, cleave peptide bonds in the main chains, and cause racemization of the amino acid residues:

$$\text{Cysteine} \rightarrow \text{dehydroalanine} + \text{hydrogen sulfide}$$

$$\text{Cystine} \rightarrow \text{dehydroalanine} + \text{thiocysteine}$$

$$\text{Dehydroalanine} + \text{cysteine} \rightarrow \text{lanthionine}$$

$$\text{Dehydroalanine} + \text{lysine} \rightarrow \text{lysinoalanine}$$

$$\text{Dehydroalanine} + \text{ammonia} \rightarrow \beta\text{-aminoalanine}$$

$$\text{Glutamine} \rightarrow \text{glutamic acid} + \text{ammonia}$$

$$\text{Asparagine} \rightarrow \text{aspartic acid} + \text{ammonia}$$

$$\text{Isoleucine} \rightarrow \text{alloisoleucine.}$$

Some of the wool proteins become soluble on degradation. The solubility of wool in alkali under standard conditions is used as an indicator of chemical changes in the fiber. Wool that has been damaged by acids, reducing agents, or oxidizing agents becomes sensitized to alkali, and its solubility in a standard solution of alkali increases.

Degradation reactions are also revealed by yellowing of the wool.

The decomposition reactions depend on the type of alkali, the temperature and duration of the reaction, the pH, and added salts and auxiliaries. Cationic surfactants increase the decomposition of cysteine and cystine and formation of lanthionine catalyzed by alkali. Nonionic surfactants have no effect on alkali damage to wool [105].

Reducing Agents. Reducing agents are used in bleaching, chlorine removal, stripping of dyes, discharge printing, production of permanent creases by ironing, and chemical setting. Reducing agents such as sodium mercaptoacetate and mercaptoethanol reduce disulfide groups to thiol groups. A 0.5 M solution of sodium mercaptoacetate dissolves wool above pH 10 in a few hours by reducing the cystine bonds responsible for insolubility:

$$\text{WoCH}_2\text{SSCH}_2\text{Wo} + 2\,\text{HSCH}_2\text{COONa} \rightarrow 2\,\text{WoCH}_2\text{SH} + (\text{SCH}_2\text{COONa})_2$$

where Wo = peptide chains of the wool proteins. Reaction of the thiol groups with iodoacetic acid produces *S*-carboxymethylkeratins:

$$\text{WoCH}_2\text{SH} + \text{ICH}_2\text{COONa} \rightarrow \text{WoCH}_2\text{SCH}_2\text{COONa} + \text{HI}$$

Reversible reduction of cystine bridges without dissolving the fiber can be achieved with thiols if the reaction conditions are sufficiently mild. This is the basis of the cold permanent waving process.

The disulfide bonds in wool can also be reduced by aqueous solutions of sodium sulfide. This reaction is of industrial importance in the production of lime wool, obtained by dehairing the skins of slaughtered sheep.

The sulfitolysis of wool is an important chemical reaction, e.g., in permanent setting. In the reaction with sulfite or hydrogensulfite, 1 mol Bunte salt (*S*-sulfonate anion) and 1 mol cysteine are produced per mole of cystine:

$$\text{WoCH}_2\text{SSCH}_2\text{Wo} + \text{SO}_3^{2-} \rightleftharpoons \text{WoCH}_2\text{S}^- + \text{WoCH}_2\text{SSO}_3^-$$

$$\text{WoCH}_2\text{SSCH}_2\text{Wo} + \text{HSO}_3^- \rightleftharpoons \text{WoCH}_2\text{SH} + \text{WoCH}_2\text{SSO}_3^-$$

Maximum cleavage occurs in the pH range 3 – 6. On rinsing, the Bunte salt and cysteine groups recombine to give wool cystine. Oxidative sulfitolysis converts disulfide into two *S*-sulfonate anions:

$$\text{WoCH}_2\text{SSCH}_2\text{Wo} + 2\,\text{SO}_3^{2-} + [\text{O}] + \text{H}_2\text{O} \rightarrow 2\,\text{WoCH}_2\text{SSO}_3^- + 2\,\text{HO}^-$$

In the reaction of wool with reducing agents, cleavage of the stabilizing disulfide bonds leads

to an increase in solubility. A linear relation exists between alkali solubility and cystine content of oxidatively and reductively bleached wool. At the same time, the enzymatic degradability increases. The dry stength does not always decrease, but the wet strength does. Plasticity increases, which is important for the process of permanent setting by deformation followed by oxidation.

Oxidizing agents attack the disulfide bonds. The reaction proceeds via various cystine oxides (sulfoxides and sulfones) and leads finally to cleavage of the disulfide bond with formation of cysteic acid. Cysteine, methionine, tryptophan, and tyrosine are also attacked. The extent of oxidation depends on the oxidizing agent and its concentration, pH, temperature, and reaction time. Of industrial importance are oxidation reactions with hydrogen peroxide (for bleaching), and with potassium manganate(VII), chlorine, peroxysulfuric acid, and peroxyacetic acid to give antifelting effects.

In the chloramide reaction, peptide bonds are chlorinated:

$$-\mathrm{CONH}- + \mathrm{Cl_2} \rightarrow -\mathrm{CONCl}- + \mathrm{HCl}$$

Photodegradation [106–113]. Wool shows only limited fastness to light. On exposure to daylight wool is bleached after a short time. After prolonged irradiation or irradiation with UV light the wool fiber yellows. Visible blue light (380 – 475 nm) is responsible for photobleaching, while maximum photoyellowing occurs with UV-B radiation (290 – 320 nm). Photodamage results in the formation of a variety of oxidation states of cystine residues, and mercaptans. Phenylalanine, tryptophan, tyrosine, histidine, and proline residues are other targets for photodamage reactions.

Scission of the main protein chain occurs with formation of keto-acyl end groups. Progressive formation of nonspecific protein cross-links (e.g., dityrosine) has also been observed.

Enzymatic Degradation. Under unfavorable conditions, wet wool is attacked by bacteria or fungi, and this can lead to damage to wool products at all stages of manufacture. Such damage can be detected microscopically by the specific color reaction with lactophenol cotton blue and by splitting of the fibers into multicellular fibrillation products, cortex cells, and macrofibrils. These (microbial) degradation reactions are caused by bacteria or fungal proteases. In undamaged wool, mainly the endocuticle and cortical cell nucleus residues are degraded hydrolytically by proteases. Macrofibrils remain intact. Damaged wool is attacked more strongly, especially at weathered fiber ends.

Enzymes are of industrial importance in wool processing, e.g., in the dissolution of skin residues from wool felts by selective degradation, and the removal of skin-scale proteins from washed wool. Enzymatic dehairing of the small hides from sheep and goats is an established process.

The use of enzymes for pretreatment and finishing is described in Sections 5.3 and 5.4.

4. Resources and Raw Materials

4.1. Sheep Rearing and Breeding [44]

Sheep growing is best suited to drier regions of the world. Steppe and savannah pastures are suitable, but tropical regions are not. Sheep have also been bred in countries with intensive agriculture, where the waste products from arable farming are used as feed. Climatic factors such as altitude, precipitation, and air temperature are important for the growth of sheep and their wool. Sheep acclimatize well, and their bodies can adapt to extreme conditions and moderate food supplies.

Depending on the climatic and economic conditions, sheep-farming countries specialize in wool production (Australia and South Africa) or the production of wool and meat (New Zealand, Argentina, and Uruguay). The crossing of English mutton rams and merino yews produces the Corriedale sheep of New Zealand. In Australia, merino rams have been crossed with Lincoln yews. These crossbreds have become established in South America as well as New Zealand, and are good producers of meat and wool. With the introduction of frozen meat technology in 1882, the crossbreds became very

important. The meat is mainly exported to the United Kingdom.

4.2. Places of Origin and Types of Raw Wool

Places of Origin. Australian and New Zealand wool; South African wool (also known as Cape wool) including Karakul and indigenous wool; European wool, e.g., German, English, Scottish, Irish, and French; South American wool, e.g., Argentinian (e.g., Buenos Aires, Bahia Blanca, and Chubut wool), Chilean (e.g., Punta Arenas wool), Uruguayan (e.g., Montevideo wool) and other South American wools from Brazil, Peru, etc.; exotic wools, e.g., from North Africa, Iran, and other Asian countries (China, India, Mongolia, etc.).

Types of Sheep. Merino wool from merino sheep or sheep of the merino type, mean fiber diameter usually $\leq 25\,\mu m$; crossbred wool from crossbred sheep, mean fiber diameter usually $> 25\,\mu m$; comeback wool from sheep obtained by crossbreeding crossbreds with merino sheep; coarse wool from coarse wool sheep, mean fiber diameter usually $> 30\,\mu m$.

5. Production Processes

5.1. Methods of Obtaining Wool [18]

By far the largest proportion of wool is obtained by shearing live sheep.

In addition, biological methods are used to recover wool from the skins of slaughtered animals. The product is known as sweated, pulled, or Mazamet wool, after the French town of that name. In New Zealand, wool recovered from skins is traded under the name slipes. It is obtained by treatment with a mixture of lime and sulfides. Reclaimed wool, obtained by disintegrating used woollen textiles, differs in having considerably shorter fibers and lower quality and purity. In accordance with textile labeling regulations, it is labeled as pure wool.

5.2. Raw Wool Scouring (See also → Textile Auxiliaries, Chap. 4.3.)

Wool obtained by sheep shearing contains varying amounts of impurities which must be removed in the scouring process. The pure wool content of raw wool is variable, the following being typical average values for Australian raw wool:

Pure wool	55 %
Wool grease	10 %
Wool suint	4 %
Soil and vegetable matter	6 – 20 %
Moisture	12 %

As wool is bought and sold on the basis of its pure wool content, the method of determining this has been standardized (IWTO-19-76).

Wool grease is highly soluble in organic solvents such as benzene, hexane, acetone, and perchloroethylene. Consequently, there have been many attempts to use these solvents in wool scouring. However, scouring with water or aqueous alcohol is also necessary to remove the wool suint, skin-flake protein, and soil impurities. Solvent-based processes are, therefore, of minor importance. Solvent scouring systems are the de Smet plant using hexane and isopropyl alcohol as solvents [146], and the Wooltech system using 1,1,2-trichloroethylene as solvent [147, 148]. However, the major wool scouring is performed today by emulsion processes. To evaluate the scouring result, the residual fat content, whiteness, ash content of the wool, and pH of the aqueous extract are determined (IWTO Methods, see Chap. 8).

In scouring machines, vigorous motion gives better washing, but can lead to a higher level of felting and hence to fiber shortening during later stages of the manufacturing process. This problem has been solved satisfactorily by the sieve-drum scouring process. Several other processes have been developed to improve wool scouring. These processes meanwhile all use suction drum bowls in combination with rake systems. The New Zealand Minibowl process and the Australian Siro Scour process have been installed in some industrial plants, but are not yet established in Western Europe.

In wool scouring, ca. 6 – 20 L of wastewater is produced per kilogram wool, depending on the process and raw wool, and even if most of the wool grease is removed, e.g., by floccula-

tion with acid and polyelectrolytes, the remaining wastewater is still highly contaminated. The pollutants still present in the wastewater can be 80 – 90 % degraded in multistage chemical and biological plants. Evaporation and incineration plants are able to destroy > 99 % of the pollutants and recover energy, water, and detergents. This has provided a satisfactory solution to the problem of wastewater purification.

Although it is no longer worth recovering potassium carbonate from the scouring water, recovery of the byproduct wool wax is economically viable (→ Waxes, Chap. 2.3.3.).

Wool-scouring plants are today mainly located in the wool-producing countries, but wool-combing plants (which are normally integrated with wool-scouring plants for cost and quality reasons) are found both in the wool-producing countries (advantage of proximity to the raw material) and in the processing countries (advantage of proximity to the market).

5.3. Mechanical Processing

Total annual wool production, expressed as pure scoured wool, is 1.4×10^6 t in 1998, of which ca. 600 000 t is converted into worsted yarn and 400 000 t into woolen yarn and carpet yarn [149].

To produce worsted yarn, the scoured wool is first disentangled by carding, which removes most of the nonfibrous impurities. The web from the carding machine is gathered to form the so-called sliver. Several slivers are combined on the first drawing frame and stretched, thereby improving uniformity. This is followed by combing, restretching, and final stretching. The back washing process once carried out before final stretching is not now usually used. The combed slivers ("tops") from the final stretching process, which have linear densities of 14 – 24 g/m, are an important commerical form of wool.

The top undergoes further combing passes to give uniformity and can be blended with other types of fiber, e.g., synthetic fibers. The "roving" is then produced by stretching on rubber rollers or on a "flyer", and this is then spun to produce worsted yarn. Ring spinning frames are generally used for this. Rotor spinning frames are now mainly used for short fibers and blends of short fibers. Several developments to increase the production of the ring spinning process, like centrifuge spinning, pot spinning, etc., are being tested in pilot plants. So far, none of these processes is used commercially

In the production of woolen yarn, the slubbing is directly produced by splitting up the carded web, and is then spun on a ring spinning machine. Both worsted and woolen yarns are converted to fabrics by the standard methods also used for other types of fiber (weaving, knitting, woven and tufted carpet manufacture, etc.).

The property of the wool fiber of migrating in various directions within the fiber bundle on mechanical treatment and in the presence of water and auxiliaries, which is due to the frictional difference, is utilized in the production of felt from loose wool (carded web) or woven materials (→ Felts, 2. Felting Process, Chap. 2., → Felts, 3. Pressed Felts, Chap. 3.). Fiber migration is also used to cause fulling of wool fabrics and carpet yarns.

5.4. Chemical Processing: Pretreatment

Carbonization (→ Textile Auxiliaries). The mechanical processes of carding scoured raw wool and of combing prior to spinning worsted yarn remove most of the vegetable matter. However, some of these impurities remain in the wool, so that the next stages of processing, e.g., the conversion of noil to wool yarn, cannot usually be carried out immediately. Noils and woolen fabrics, which sometimes also contain unacceptable amounts of vegetable matter, are therefore carbonized. This name is derived from the fact that the impurities, which consist mainly of cellulose, form dark to black carbonization products after impregnation with sulfuric acid and heating. These can then be removed from the fiber bundle because of their brittleness.

In recent research, the use of enzymes to remove vegetable matter is being investigated [150, 151].

If carbonized material is not dyed while it is still wet and contains acid, the fabric must be protected from the effects of moisture and light, and the storage time must be as short as possible. Also, the dyeing method used must be as mild as possible.

Antifelting Treatments. Most of the antifelting treatments developed for wool modify the surface of the fiber by chemical attack. This affects the scales such that the difference between the "roughness" of the fiber surface in the tip-to-root and root-to-tip directions is reduced or even eliminated. At one time it was believed that antifelting treatments had to remove the surface scales entirely. It is now known that this is not so; a treated fiber will often look no different from an untreated fiber under the microscope [29].

Antifelting finishes work by partially removing, softening, or coating the scale layer, or by preventing movement of the fibers relative to each other by spot welding. Treatment with adhesives can only be used on the finished fabric, whereas the other processes can also be used on tops. They include chlorination and treatment with manganate(VII) or peroxysulfuric acid. This must be carried such that only the scale layer is attacked and not the interior of the fiber. Precise process control gives very good stability to washing accompanied by low losses in weight and strength.

A process widely operated in Germany that can also be used on the top is a combination of relatively mild chlorination followed by treatment with a polyamide – epichlorhydrin resin (e.g., Hercosett 125). This is today the most important process for the production of machine-washable articles of pure wool, and gives products complying with the specifications of the IWS Super Wash mark. The chlorination stage of the process is carried out with hypochlorite, whereas the Kroy process uses gaseous chlorine. In 1994, the total quantity of wool sliver treated worldwide in accordance with the IWS Super Wash specifications was ca. 25 000 t.

The so-called Vantean process, an oxidative process developed in Japan, comprises the following steps:

1) Pretreatment with heavy metal ions (can be omitted)
2) Treatment with hypochlorite in a saturated, strongly acidic salt solution
3) Treatment with sulfite
4) Stabilization with formaldehyde

The process removes the cuticle almost completely, and gives the wool a luster resembling that of much more expensive fine animal hairs. For ecological reasons, work is directed towards the development of a new antifelting process that does not use chlorine or chlorine compounds [152].

The most promising developments so far are treatment with peroxysulfuric acid and manganate(VII), but a commercial process of this type for tops treatment is not yet available.

Research is being carried out into antifelting effects produced by plasma technology [119] or topochemical enzyme processes [120]. Recently, an environmentally friendly procedure for antifelting treatment of wool was developed, involving replacement of the conventional chlorination by a treatment with a low-temperature plasma, followed by application of a new developed polyurethane based polymer [153–156]. The development in plasma technology is far advanced and tests with a pilot plant are running. A commercial process will be available in the next years.

Bleaching of wool is not as important as the bleaching of natural cellulose fibers. For many purposes, the natural cream color of wool is acceptable, e.g., for garments finished in this color or for those dyed in dark shades. For white articles and sometimes for pastel shades, the wool must be bleached, preferably with hydrogen peroxide (see → Textile Auxiliaries).

Naturally pigmented dark wool fibers require special treatment. Although they are present in very small numbers in high-quality wools (a few naturally colored fibers in 10 g wool), they have a detrimental effect on the appearance of garments dyed in pale shades. The colored fibers can be selectively bleached by a process in which the wool is pretreated with an iron salt, carefully washed, and then bleached with hydrogen peroxide [121].

For carpet wools, bleaching during raw wool scouring, simply by adding hydrogen peroxide or reducing agents to the last bowl, is a process of some importance. This practice can lead to increased wool yellowing during dyeing but is commercially attractive because the whiter wool attracts a higher price.

The highest level of whiteness can be obtained by a combination of bleaching with hydrogen peroxide and reductive bleaching with, e.g., Blankit products, which contain sodium

dithionite and sometimes also an optical brightener. However, care has to be taken in this bleaching process as fiber damage can occur.

Bleached and, to an even greater extent, optically brightened wool undergoes more yellowing than unbleached wool on exposure to light. Solubility in alkali is a sensitive indicator of bleaching damage to wool (see page 13). However, it is possible that although the alkali solubility (30 %) may be twice its normal value (12 – 17 %), a decrease in breaking strength of only 2 – 5 % occurs.

New Developments. In the last few years there has been a growing demand for elastic fabrics and easy care properties, not only for sports and leisurewear but for formal wear also, particularly for wool and wool rich trousers (Wool plus Lycra). The disadvantage of elastomeric fibers in the fabric is that these fibers are not dyeable to the fastness standards of the main fibers in the cloth. Some natural stretch can be produced in wool fibers by subtle yarn technology, however, a 20 % stretch requires the application of reducing agents. Sulfite-based textile auxiliaries were developed that provide worsted wool fabrics with a natural stretch [157]. This permanent elasticity of yarns and fabrics is achieved through supercontraction of the wool fiber.

A new technology for reduction of the fiber diameter of wool fibers has been developed by Woolmark Company and CSIRO; both, process and wool fibers have the trade name OPTIM [158, 159]. OPTIM fine (permanently stretched fiber) reduces the diameter of wool by 3 – 4 µm. Another variant, OPTIM max (temporarily stretched fiber) is a fiber which is able to shrink by 20 to 25 % so that a higher bulkiness and softness is achieved. The process combines a stretching and either permanently or temporarily set in stretched configuration ($\alpha \rightarrow \beta$ transformation) so that a new wool fiber with different chemical and physical characteristics is produced [135], due to the $\alpha \rightarrow \beta$ transformation OPTIM fine has a more silk-like character than untreated wool [159].

5.5. Dyeing and Finishing [37, 40, 45, 50]

Dyeing and Printing. Dyeing is the most important wet finishing process for wool. Wool can be dyed in most stages of its manufacture, i.e., as flock, slubbings, yarn, or piece. The dyeing of flock is of importance in the production of melange shades, of woolen yarn consisting of blends with other types of fiber or of large batches of uniform shades. The dyeing of sliver is useful for the production of large batches of completely uniform color. Color discrepancies can usually be leveled by mixing slivers without additional dyeing. Dyeing of wool blends is described in [45, Chap. 9].

The dyeing and printing of wool are treated in detail in → Textile Dyeing, Chap. 5.1., → Textile Printing, Chap. 7.). The most important dye classes for wool dyeing are afterchrome dyes (ca. 25 – 30 %), acid dyes (ca. 25 – 30 %), 1 : 1 metal-complex dyes (ca. 7 %), 1 : 2 metal-complex dyes (ca. 30 %), and reactive dyes (ca. 10 %) [160]. Chrome dyes continue to fulfill a high proportion of wool dyeing capacity, particularly as a cost effective, high-wetfastness system for slubbings and loose wool. Chromium residues (especially Cr(VI)) in the dyed textiles can cause allergies and toxic skin reactions in sensitive individuals. Due to the allergic and toxicological potential of chromium the usage of afterchrome dyes for wool dyeing is strongly decreasing. Furthermore, residual chrome creates a problem in dyehouse wastewater. This has been minimized by the use of modified chrome dyeing techniques [122–124].

Reactive dyes represent an alternative method of achieving the high wetfastness of chrome dyes whilst eliminating the problem of heavy metal contamination of dyehouse, scouring liquors, and dyed textiles [161].

The tenacity of wool is often reduced in stock-dyeing processes. As a result of this, many fibers are broken in the card. Most of the reduction in fiber strength is due to setting of bends or curvatures of the packed fibers by the hot water treatment. Such set fiber bends are nonuniformly strained by tensions and thus resist smaller loads than fibers set in the straight state [129].

In addition to the minimum wool damage exerted due to their optimum application pH in the isoionic region, reactive dyes further enhance wool quality by chemical reaction with thiol groups, H_2S, and histidine side chains, and by acting as antisetting agents [125–128].

Research studies have been performed to dye wool from nonaqueous media, i.e., from super-

critical carbon dioxide [162, 163]. Wool can be dyed from supercritical carbon dioxide with hydrophobic dyes, improved fastness properties are achieved by application of reactive disperse dyes [162, 163].

Setting. According to DE BOOS [130], setting is an essential feature of the finishing of wool fabrics. It is used to stabilize fabrics prior to scouring and dyeing, to provide the required thickness, handle and visual properties to fabrics, to provide some durability to the final finish, and occasionally to minimize dimensional changes in subsequent tailoring and wear. For these reasons, setting is an integral part of good finishing and fabric quality. Cohesive set in wool fibers is thought to involve rearrangement of the hydrogen bonds in the fiber, and is imparted whenever wool is distorted at temperatures above the glass-transition temperature (Fig. 12) of the fiber and cooled while distorted. This set configuration of the fabric is stable as long as the fibers remain below their T_g.

Permanent set in wool requires the rupture of disulfide bonds in addition to the hydrogen bonds in the fiber. Most authors [131, 132] believe that thiol – disulfide exchange reactions at temperatures in excess of 60 °C are required to impart permanent set. Others [131–135] consider the "transition temperature" for the onset of thiol – disulfide exchange reaction as the temperature required for chemical cysteine degradation and H_2S formation (see page 13).

The decisive role of cysteine thiol groups as initiators of the reactions that lead to permanent set is common to both theories. Thus, all industrially proven methods of minimizing dyeing damage due to permanent set are based on the same principle, i.e., blockage or oxidation of the cysteine thiol groups during dyeing [136, 137].

The effectiveness of reactive dyes or other reactive chemicals is due to the fact that they block not only the cysteine thiol groups, which decreases the rate of H_2S formation, but also amino groups of the wool proteins, preventing the catalysis of cysteine degradation reactions.

Shrink-Resistant Finishes. Fabrics or garments can be treated with nonchlorination processes which utilize polymers alone (→ Textile Auxiliaries, Chap. 7.6.5.).

Protection from Moths and Beetles [138–141]. See → Insect Control, Chap. 14.4..

Permethrin-based insect-resist (IR) products account for ca. 90 % of the European market, based on the volume of treated wool. Permethrin-treated wool has poor fastness to moisture and light, so that treatment with these products is recommended mainly for carpets and for storage protection.

Conventional wool-specific protection agents based on Sulcofuron are Mitin FF h.c. (80 % AS, Ciba Specialty Chemicals), and Mitin FF liquid (Ciba Specialty Chemicals). Wool treated with Mitin FF has very good fastness towards moisture and light, and is therefore suitable for articles from which high standards of colorfastness are demanded.

Sulcofuron

Permethrin

Mothproofing agents are usually applied during the exhaustion dyeing process, i.e., are added to the dyebath and are taken up by the wool with the dye. Other possible methods include application during scouring.

Flameproofing. Wool is less flammable than cellulose and synthetic fibers (see → Textile Auxiliaries, Chap. 7.5.). Its high ignition temperature, high limiting oxygen index, low heat of combustion, and low flame temperature are particularly advantageous and are connected with the chemical and morphological structure of the wool fiber, which has high nitrogen (16 %) and moisture (10 – 14 %) contents.

Negatively charged titanium and zirconium complexes with α-hydroxycarboxylic acids and fluorides can be exhausted on the positively charged wool fiber in acid conditions, the result being a significant improvement in the natural flame resistance of wool that is fast to washing and dry-cleaning. The complexes with carboxylic acids are exhausted on the wool fiber

at the boil, whereas the fluoride complexes can be effectively exhausted at lower temperatures. The fluoride complexes can also be applied by a pad – batch – rinse – dry technique. Titanium complexes are more effective than the zirconium ones, probably because of better penetration of the fiber by the smaller titanium complexes. However, titanium complexes cause yellowing of wool, which increases with light exposure. Zirconium complexes do not affect the shade of wool and are fast to light [142].

Lightfastness Treatment. The effect of light on wool is first to bleach it (photobleaching) and then to cause yellowing (photoyellowing). For interior woolen textiles photobleaching is the main problem because window glass filters short-wave UV light which induces photoyellowing. However, visible light (especially blue light, i.e., light with a wavelength of 400 – 450 nm), which causes a marked photobleaching, passes window glass. A new approach was developed by WRONZ-Institut to prevent photobleaching by application of a sulfonated aromatic compound (Lanalbin APB) [164].

Photobleaching is especially marked when woolen textiles are also thermally stressed (e.g., in automobiles). The lightfastness of wool, including bleached and dyed wool, can be improved by the application of sulfonated UV absorbers, hydroxybenzophenones (Uvinuls) or hydroxybenzotriazoles (Cibafast W) from the dyebath [143–145].

Cibafast W

Hydrophobization and Oleophobization Treatments. If necessary, wool, like other fibers, can be made water- and oil-repellent by treating it with silicones or fluorinated hydrocarbons.

6. Environmental Protection

Like the other organic natural fibers, cotton and silk, wool is an environmentally friendly, renewable textile raw material. Woolen materials are reusable. Wool wastes are biodegraded by bacteria, fungi, and insects (moths, carpet beetles) and can be used as long-acting nitrogen fertilizers [165].

Wool production and wool industry, however, are faced with wastewater limitations due the pesticide residues in the clip [166], the highly polluted wool scouring effluent (see Section 5.2) [167], AOX in the shrink-resist processes, chromium in the dyeing process [168, 169], and the application of insect resist (IR) agents [170]. Dyeing and finishing with minimum environmental impact is crucial to the manufacture of eco-textiles [171, 172].

Modern effluent treatment removes pollutants by ecologically tolerable processes. By strict compliance with dyeing instructions the chromium(VI) content in the effluent can be kept within tolerable limits. Legal and environmental aspects of the textile finishing industry are described in → Textile Dyeing, Chap. 14.; → Textile Auxiliaries, 1.4 Environmental Aspects, Chap. 1.4., → Textile Auxiliaries, 4.4 Ecological Aspects of Fabric Pretreatment , Chap. 4.4.

A detailed and authoritative account of the environmental aspects of wool production and wool processing is afforded by the published proceedings of the two quinquennial wool textile research conferences, held in 1990 and 1995 [42, 52].

7. Quality Specifications [48, 53, 173]

Testing methods are described in → Fibers, 6. Testing and Analysis, 2. Tests of Form and Mass, Chap. 2., → Fibers, 6. Testing and Analysis, 3. Tensile Properties, Chap. 3. Quality of wool or tops implies a statement of the type, origin, and spinnability of the raw wool. An important quality criterion is mean fiber diameter (fineness), which influences the softness of hand and is of paramount importance in spinning. Price is determined mainly by fineness.

Wool fineness is specified by the mean fiber diameter in micrometers. In the past, there were various systems of quality specification, e.g., as used by spinners, merchants, and sheep farmers. The most important systems are the British (numbers ranging from 100's to ca. 36's), French

(numbers in the ranges 150 – 100, I – VI, and C), and German [letters in the range AAAA (4 A) to A, B, etc., up to EE]. Table 4 compares the British system with mean fiber diameter and fineness. Recently British mills have agreed that the existing micron definitions should be extended for superfine wools to 100's – 200's (i.e., 17.0 to 13.5 µm mean fiber diameter), because of increased demand for fine fabrics for traditional tailoring.

Table 4. British quality numbers, mean fiber diameter, and mean fiber fineness [44]

British quality number	Mean fiber diameter, µm	Mean fiber fineness, dtex
90's	≤17	≤3
80's	17 – 18	3 – 3.3
74's	18 – 19	3.3 – 3.7
64's	21	4.5
60/64's	22	5.0
60's	23	5.4
58's	25	6.4
56's	28	8.1
50's	33	11
48's	34	12
46's	37	14

The British grade number gives the number of hanks of 560 yards (512 m) that can be spun from 1 lb (453.6 g) of wool (spinning limit).

For fine yarns, i.e., those with on average ca. 35 fibers in the cross section, wool-fiber-diameter distribution affects spinning performance, as well as yarn evenness and tensile properties. Effective fineness, a parameter derived from yarn-evenness theory, is a better predictor of (fine) physical yarn properties than mean fiber diameter alone [174].

There are two systems for obtaining an objective measurement of hand. In the *Kawabata System*, 17 fabric properties relevant to the hand are determined with four measuring devices. These enable statements to be made about the stiffness, elasticity, and surface condition of the fabric, and objective dimensionless hand indices can be calculated from these if required [175, 176].

In the *FAST System* (Fabric Assurance by Simple Testing), 14 fabric properties are determined using three compact instruments. When these are plotted on a multiaxial graph (the so-called fingerprint), conclusions can be drawn about the processing properties of the fabric during manufacture [177].

8. Testing and Analysis [46, 48]

Chemical methods of testing wool to assess damage at the various stages of manufacture are well established. The use of a combination of methods enables the causes of impairment of mechanical properties to be elucidated with a high degree of certainty. The methods include the determination of foreign substances (wool grease, spinning oils, ash, etc.), amino acids [178], and alkali or urea – bisulfite solubility.

It is not possible to quote mandatory values of mechanical and chemical data for a given wool. It is only possible to collect typical values for undamaged wools [179]. These analytical data vary on wet finishing of the wool in various directions and to various extents. Only in the case of certain standard treatments, such as carbonization, peroxide bleaching, or chlorination, can definite tolerances be given which must not be exceeded after a correctly performed process in order to ensure a defect-free product. Reliable figures are obtained if samples are taken by standardized methods at the various stages of a treatment process and analyzed. Most chemical testing methods for wool have been standardized by the Technology and Standards Committee of the International Wool Textile Organization (IWTO) [180].

The most important criteria for the assessment of changes to wool caused by industrial processing, especially wet finishing, are mechanical properties such as ultimate tensile strength. The dry and wet strength and elongation of yarn bundles are determined (IWTO method 32-1982). The dry values for undamaged wool are in the range 10 – 12 cN/tex, but these can decrease on dyeing. Decreases by up to 15 % of the maximum ultimate tensile strength are acceptable for finishing processes.

Efficient separation methods for amino acids and proteins by chromatography and electrophoresis (see → Amino Acids, Chap. 6.) are applied in wool research for estimation of lanthionine, lysinoalanine, histidinoalanine, cysteic acid in hydrolysates of wool and *S*-carboxymethyl proteins in mercaptolytic digests. One-dimensional electrophoresis allows up to 50 distinct wool proteins to be separated (Fig. 13). Comparison of electrophoretic patterns of digests of dyed and finished wool textiles allow specific statements on the involvement

of morphological components and chemical constituents, such as keratins versus keratin-associated proteins [181–184].

Figure 13. Schematic electrophoretic protein-separation pattern of merino wool [183]

9. Storage and Transportation [185]

Wool must be stored and transported under normal atmospheric conditions. Bales of raw wool, scoured wool, tops, or any other form should be kept dry to avoid bacterial and fungal attack. The packaging material must allow some exchange of air to avoid damp and high-humidity conditions in the bale. The wool pack material should not pose problems in dyeing and finishing.

10. Uses [32]

Merino and crossbred wools are mainly used in clothing, home textiles (carpets, domestic furnishings, and bedding), to some extent in automobile upholstery (most often blended with polyester) and in aircraft seatings [186–188]. According to [189], the wool fiber can now be found in applications as diverse as thermal insulation, weed mats, geotextile products, and as a means to soak up oil spills. Wool has been used for thermal insulation in houses in Europe for many decades and is being increasingly used for both homes and commercial buildings [190–194]. The natural property of wool to effectively absorb specific classes of widespread indoor air pollutants, namely aldehydes, SO_2 and NO_x, has led to new applications in the private and commercial sector [195–197]. Wool is naturally fire resistant, and the increased use is being driven by consumer demand for natural products in their homes. The moisture absorbing and desorbing properties of wool can also contribute to passive heating and cooling effects and, led, furthermore, to the use of wool for high-performance sportswear clothing. Of minor importance are special wool products, especially felts, e.g., for filter materials.

Keratin hydrolysates can be isolated from wool by acid, basic, or enzymatic hydrolysis in combination with a reductive (or sometimes oxidative) treatment. These hydrolysates are used as fiber protective agents during wool dyeing [198], for cosmetics, or for production of new textile materials [199]. L-Cystine can be isolated from hydrolysates of hair or wool (see → Amino Acids, Chap. 3.2.4.).

11. Trademarks

The Woolmark Company was founded in 1937 as the International Wool Secretariat. Today it is known as The Woolmark Company and is the world's leading wool textile marketing organization. Together with its three well known trademarks, it is synonymous with research and

development, innovation, promotion, and quality assurance in pure new wool and wool blend products (cf. http://www.wool.com).

The *Woolmark* symbol was designed by an Italian, Franceso Sarroglia to identify quality products made from pure new wool (Fig. 14). Textiles with this mark must consist of 100 % virgin wool. Admixtures of wool recovered by mild methods from the skins of slaughtered sheep are permitted. Equal status is given to fine animal hair from the alpaca, llama, vicuna, guanaco, camel, angora, rabbit, angora-mohair, cashmere and cashgora goats, and yak, provided that here also it is obtained by a mild process. The Woolmark was launched in 1964, and is now a registered trademark in over 140 countries. It is used by companies licensed by the Woolmark Company in more than 65 countries extending across a wide range of products – clothes, carpets, home furnishings, washing machines and detergents. In 1970, the designation "pure new wool" (Reine Schurwolle) was included in the textile labeling law (TKG) of the Federal Republic of Germany, and became valid in the European Community in 1972. The *Woolmark Blend* symbol (originally called Woolblendmark) was introduced in 1971 to identify quality products made from wool rich blends (products comprising at least 50 % new wool). The *Wool Blend* symbol was introduced in mid-1999 to extend the opportunities offered by The Woolmark Company's blends program; the Wool Blend symbol is used to identify products that contain at least 30 % (but less than 50 %) new wool (Fig. 14).

The same high performance standards apply to all three trademarks. Before a manufacturer can use the Woolmark or any trademarks of the Woolmark Company he needs to apply for a license, and pay the relevant usage fee [200]. He also needs to be able to meet the quality standards that are required under the Woolmark program. Maintaining consistent high quality is a key feature of the Woolmark program, and it is important that all licensees have good in-plant quality assurance procedures in place.

In addition to its three main brands, the Woolmark Company has introduced a series of programs, which highlight selected product attributes. These programs are backed by specifications and clear product descriptions to ensure a clear and globally consistent message. Each program is also identified by a specially designed sub-brand logo; the logos are featured on a range of promotion tickets, including Cool Wool, Merino Extrafine, Pure Merino Wool, Machine Washable Wool, Total Easy Care Wool, Wool plus Lycra [201], Wool Cotton, Sportwool [159]. Further details are available from The Woolmark Company at http://www.woolmarkbrand.com.

12. Economic Aspects

Wool Production. Table 5 gives world wool production figures for the major producing countries during the period of the shearing seasons from 1995/96 to 1999/2000; Figure 15 shows percentage shares of world production. Table 5 shows actual weights of raw wool or lime wool.

Wool production has grown only slowly over recent decades, as grazing land for sheep cannot be increased indefinitely. A decline has even occurred since 1990/91 for reasons of climate, price (lucrative alternatives for farmers), and political economy (economic decline in Eastern Europe).

Sheep rearing and hence wool production exist in almost all parts of the world, although at widely varying levels of intensity. In most countries, home-produced wool is processed and consumed internally, and therefore is not available on the international market. This also applies to important wool-producing countries such as China and the countries of the former Soviet Union. The suppliers of the raw material to the international wool textile industry are those countries that produce and export amounts of wool in excess of their own requirements. These principally comprise Australia, New Zealand, Argentina, Uruguay, and South Africa.

Australia is the world's largest producer and exporter of garment wools (merinos), exporting ca. 60 % of its wool production as raw wool, and thus being the most important supplier for the wool combers of the industrialized countries. New Zealand produces mainly scoured coarse wools that are exported for use in the production of home textiles, especially carpets. Argentina, Uruguay, and South Africa have also built their own wool scouring and combing plants, and export wool either in scoured loose form or as tops (scoured and combed wool). Table 6 lists

Figure 14. Woolmarks for pure new wool and new wool with other fiber

wool export figures, for the five most important exporting countries for the seasons 1994/95 to 1998/99.

Figure 15. World wool production (1997/98)

Wool Prices. The price differences between the various wool qualities are considerable. The most important factors determining quality and therefore price are the fineness and staple length of the fiber. Not only the mean fineness and length, but also the uniformity of distribution are of great importance. Other quality and price parameters are the content of vegetable matter and pigmented fibers, tensile strength, color, elasticity, crimpiness, and many others.

Since the collapse in early 1991 of the minimum price system which imposed a lower limit on wool prices for 17 years in Australia, New Zealand, and South Africa, prices have been determined by the market forces of supply and demand. Figure 16 shows the development of the average auction price of Australian raw wool, the so-called market indicator (i.e., the weighted average of the qualities) in the sales seasons 1994/95 to 1999/2000. The market indicator during this period fluctuated between 5.1 A$/kg (March 1999) and 8.6 A$/kg (March 1995).

However, the price differences between two given qualities can vary greatly over time with supply and demand. This is illustrated in Figure 16, which also shows the price curve for 19 µm wools. The difference in price between this and the market indicator varied between 0.80 A$/kg (March 1996) and 7.85 A$/kg (September 1994). The reasons for the relatively low prices for fine wools may be an increased supply of "hunger-fine" wools after a drought, and the lack of interest in such low-quality, albeit fine wools. A high price is evidence of a strong,

Wool Consumption. Table 7 lists world wool consumption. Europe has the highest consumption of wool (36 % of the world total). This underscores the world importance of the European woolen industry. The four EU countries Italy, Germany, United Kingdom, and Spain account for 29 %, the rest of Western Europe 14 %, and Central and Eastern Europe 8 % of total world consumption for spinning mills. In second place is the Far East, with 28 % of the total world industrial demand for wool. For German wool imports, see Table 8.

The comparatively minor importance of the wool textile industry in the United States, i.e., 3 % of the world's consumption of virgin wool, is remarkable.

13. Toxicology and Occupational Health

The wool fiber itself poses no health problems. On the contrary, woolen clothing protects against heat, cold, water, and sun as well as mechanical impact [203].

Wool products that have reached the end of their useful life may be recycled via the woolen

Table 8. German imports of wool and tops (in t) (Source: Comtext, Eurostat)

Import Category	1999 (full year)	Jan – April 1999	Jan – April 2000

process and can be used for production of wool materials of minor quality or technical products. Wool is biodegradable. However, pretreatments or presence of contaminants such as pesticides or textile finishing agents like mothproofing agents, flame retardants or dyes have impact on the ecotoxicology of wool materials.

Prickle [204–208]. No health risks are involved in wearing properly finished and dyed wool clothing, even if it comes in direct contact with the skin. Wool incompatibility is caused neither by toxic components of wool, nor is it a wool allergy; it is a purely mechanical irritation of the skin.

Wool prickle is due to the coarser wool fibers digging into human skin with enough force to excite pain receptors. Fabrics made from wool with no more than 5 % of fibers larger than 30 µm will not be perceived as prickly by most people.

This mechanical skin irritation is not specific to wool, but can be caused by other natural and synthetic fibers if sufficient coarse fiber ends per unit area of skin are present.

Azo Dyes [209–211]. Properly dyed wool articles do not contain such azo dyes that could set free carcinogenic aromatic amines such as benzidine.

Members of the Ecological and Toxicological Association of Dyes and Organic Pigment Manufacturers (ETAD) ceased the manufacture of benzidine-based dyes in the early 1970s due to the inability to ensure their safe handling in dyeing plants. However, because of the particular economic and technical merits of these dyes, they have continued to be manufactured in many countries. Provided the dyed goods have good fastness characteristics, there is not a concern about consumer risk.

Occupational Health. For the ecotoxicological potential of textile dyes, see → Textile Dyeing, Chap. 14.7..

In the processing of wool, problems are caused by exposure of workers to noise and to respirable and alveolar dust [212, 213, 215].

There is a potential human health hazard to shearers and farm workers handling the treated sheep and wools. Users of lanolin products are at lower risk, especially if the commercially available "reduced pesticide" grades of lanolin are used where there is human skin contact. All the existing ectoparasiticide products are evaluated for potential hazard to shearers and farm workers for incorporation into the protocol of the Australian Occupational Health and Safety Commission. As measure of the "safe exposure level" the acceptable daily intake is compared with the potential exposure calculated from the amount of active ingredient present and the amount of wool grease covering the shearer [214]. However, the use of toxic agents for sheep dips, etc., is today discouraged and nonharmful alternatives are recommended. Also operational procedures are now strictly laid down to control and minimize any risks to farm workers, etc.

Acknowledgement. The authors thank Hartwig Höcker (Director of the Deutsches Wollforschungsinstitut an der RWTH Aachen) for checking the manuscript and Klaus Wolf, Hans-Georg Hebecker, Peter Duffield, and Kevin Russel for helpful suggestions.

1. Introduction

According to the IUPAC nomenclature, xanthates or xanthogenates (older name in the continental literature) are described as derivatives of *O*-alkyl- or *O*-aryldithiocarbonates (xanthic acids; **1**). The term xanthates refers both to the salts of the general formula **2** and to the corresponding *O*,*S*-diesters **3**.

The name xanthogenates (derived from the Greek *xanthos*: yellow) was introduced by ZEISE, who discovered this class of compounds in 1822 [8].

2. Physical Properties

Xanthic Acids. The free xanthic acids (**1**) are oily liquids, that are stable only in the pure state. They are strong acids, the dissociation constants of the C_1-C_5 esters in water are in the range of $1.4-3.4\times10^{-2}$ [9]. Xanthic acids are readily soluble in nonpolar solvents and sparingly soluble in water. Traces of polar substances cause their decomposition into carbon disulfide and the corresponding alcohol. The alcohol formed accelerates the decomposition autocatalytically.

Alkali-Metal Xanthates. In contrast to the free acids, alkali-metal xanthates are relatively stable, yellowish solids of unpleasant odor. The potassium xanthates crystallize without water, whereas the sodium salts form dihydrates upon exposure to atmospheric moisture. The melting points of some industrially important alkali-metal xanthates are given in Table 1. Since the potassium salts melt with decomposition, very different melting points are found in the literature [10].

Alkali-metal xanthates are soluble in water and polar organic solvents such as alcohols, lower ketones, pyridine, and acetonitrile, but sparingly soluble in nonpolar solvents, e.g., ether or petroleum ether. The solubilities of some alkali-metal xanthates in water and alcohols are given in Table 2.

Heavy-Metal Xanthates. The heavy-metal xanthates have lower *mp*s than the corresponding alkali-metal salts and are better soluble in organic solvents, e.g., chloroform, tetrahydrofuran, and carbon disulfide, than in strongly polar ones [11]. The solubilities of heavy-metal *O*-ethyl xanthates in water increase in the order Au^+, Hg^{2+}, Cu^+, Ag^+, Pb^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Fe^{2+} [12].

Aqueous xanthate solutions are relatively stable between pH 8 and 13 with a maximum of stability at pH $\approx$ 10 [13], but they rapidly decompose at pH $<$ 6 and at pH $>$ 13 (see Chap. 3).

Their stability tends to increase with increasing molecular mass and branching of the alkyl group.

The electron absorption spectra of aqueous xanthate solutions show characteristic bands at 301 and 226 nm with extinction coefficients ε of $\approx$17 500 and 8750, respectively [14]. IR spectra of various xanthates have been published, e.g. [15].

3. Chemical Properties

In the presence of polar substances xanthic acids readily *decompose* into carbon disulfide and the corresponding alcohol, which accelerates the decomposition autocatalytically [16].

This reaction is also the second step in the decomposition of xanthates in aqueous acidic solution [17]:

In neutral and alkaline solutions xanthates *hydrolyze* according to the following equation. The trithiocarbonate formed can decompose further into carbon disulfide and hydrogensulfide.

Xanthates are susceptible to *oxidation*, resulting in the formation of dixanthogens, e.g.:

Oxidation can be accomplished by various oxidants [18], e.g., oxygen, chlorine, bromine, iodine, hydrogen peroxide, nitrous acid, and chloramine T. In addition, oxidative coupling is achieved by anodic oxidation [19]. Diisopropyl dixanthogen, used as polymerization regulator,

is produced by oxidation of potassium isopropyl xanthate with persulfate [20].

Condensation of alkali-metal xanthates with sulfur dichlorides gives higher xanthate sulfanes [21].

Alkylation of alkali-metal xanthates with alkyl or allyl halides yields the corresponding xanthate esters (*O*,*S*-diesters of dithiocarbonic acid).

This widely employed synthetic procedure [22] is usually carried out in organic solvents such as ethanol, ethers, ketones, or benzol under reflux, but reaction in DMSO is also possible [23]. In aqueous solution, alkylation is often conducted under phase transfer conditions [24] or in the presence of an emulsifier [25]. Especially in industrial processes, alkylation is carried out as a one-pot reaction without isolation of the corresponding alkali-metal xanthate [26]. Xanthate esters have also been obtained by alkylation of polymer-supported ammonium xanthates [27]. Treatment of lithium enolates with carbon disulfide and subsequent alkylation gives α,β-unsaturated esters [28].

Reaction of alkali-metal xanthates with geminal dihalides affords the corresponding bisxanthates [29].

In contrast to alkylation, *arylation* of alkali-metal xanthates is possible only with aryldiazonium salts [30]. In the Leuckart reaction, the arylesters thus obtained are converted either to thiophenols by hydrolysis [31], or thermally to thioethers.

Mild *pyrolysis* of *S*-methylxanthates results in elimination of carbonyl sulfide and methanethiol to give the corresponding alkenes without rearrangement (Chugaev reaction) [22,32]. This reaction is widely used to convert alcohols into alkenes via their *S*-methyl xanthates.

Applications in peptide chemistry [33] and in the terpene field have also been described [34].

Treatment of xanthate esters with tributyltin hydride gives *deoxygenated products* by radical reduction (Barton – McCombie deoxygenation) [35].

This method is efficiently applied in the deoxygenation of secondary alcohols [36] and of secondary hydroxyl groups of carbohydrates and nucleosides [37].

Other reagents effecting radical deoxygenation of xanthates include various silanes [37,38], dialkyl phosphites [39] and hypophosphorus acid or its salts [40]. Analogously, deoxygenations of primary [41] and tertiary alcohols [42] have been achieved via the corresponding xanthates.

Application of this deoxygenation procedure to bisxanthate esters derived from vicinal diols affords the corresponding alkenes [43].

Several interesting *radical cyclizations* involving xanthates have been described. Thus, five- to eight-membered cyclic ethers [44], five- and six-membered *N*-heterocycles [45], and thionolactones [46] have been synthesized by this procedure.

Xanthate esters undergo thermally induced *rearrangement* to give *S*, *S*-dialkyldithiocarbonates [23,47].

This isomerization can also be effected catalytically with a Lewis acid or trifluoroacetic acid [48]. The isomerization of *O*-allyl xanthate esters occur with simultaneous allyl rearrangement [49].

Alkali-metal xanthates react with alkyl chloroformates to give alkyl xanthogen formates (mixed anhydrosulfides) (**i**), together with dialkyl xanthic anhydrides (**ii**), dialkoxy carbonyl sulfides (**iii**), and dialkyl carbonates (**iv**) as coproducts.

These reaction mixtures are used as collectors in the flotation of copper – molybdenum sulfide ores [50]. Efficient methods for obtaining the xanthogen formates (**i**) as the sole products in nearly quantitative yield have been also described [51].

4. Production

4.1. General

Alkali-metal xanthates are principally synthesized by reaction of an alcohol with sodium or potassium hydroxide and carbon disulfide. This reaction consists of two steps: (1) the formation of the alkali-metal alkoxide; and (2) reaction of the alkoxide with carbon disulfide to give the xanthate.

This reaction is applicable to all types of alcohols, including diols, polyols, and carbohydrates, including starch and cellulose. Xanthate salts of primary and secondary alcohols are prepared in aqueous medium, whereas the corresponding derivatives of tertiary alcohols are readily hydrolyzed and are therefore synthesized under anhydrous conditions [52]. Analogous reactions of solid alcohols [52] and of phenol and its derivatives [53] are carried out in aqueous dioxane.

For several purposes (when they are, for example, used as intermediates in the synthesis of xanthate esters) isolation of the alkali-metal xanthates is not necessary. Here, the xanthate is obtained in high yield by converting the alcohol into the corresponding alkoxide with metallic sodium or sodium hydride in an inert solvent and subsequent addition of carbon disulfide. This procedure is also suitable for unsaturated alcohols, e.g., allyl and propargyl alcohol [54].

Another preparation method for alkali-metal xanthates is the reaction of a dialkyl ether with alkali hydroxide and carbon disulfide [55].

Water-insoluble *heavy-metal xanthates* can be prepared by reaction of dissolved alkali-metal xanthates with heavy-metal salts [5].

Reaction of carbon disulfide with epoxides affords *cyclic dithiocarbonates* (1,3-oxathiolane-2-thiones) [56].

The corresponding 4,5-unsaturated heterocyclic derivatives are obtained by rhodium-catalyzed decomposition of α-diazocarbonyl compounds in the presence of carbon disulfide [57].

4.2. Production Processes

In the industrial production of alkali-metal xanthates a primary or secondary C_2-C_6 alcohol is reacted first with anhydrous sodium or potassium hydroxide and subsequently with carbon disulfide. To avoid side reactions, e.g., thermal decomposition, the temperature of the reaction mixture is generally maintained below 40 °C by cooling. Since their introduction into flotation in 1925, detailed reaction conditions of the manufacture of xanthates have been evaluated and described in numerous patents. In principle, the reaction can be carried out with or without a solvent.

Production without solvent is carried out in reactors preferentially made from steel that contain cooling and stirring apparatus. The reactors are also equipped with a heating device so that the reaction and the drying of the product can be carried out in the same vessel. Several improvements of the existing methods are reported in the patent literature. Thus, a reactor for the production of alkali-metal alkyl xanthates in one step with economic raw materials utilization and without environmental pollution is described [58]. Another patent reports increased yields and improved quality of xanthates by carrying out the process in a rotor-plate reactor [59]. Potassium butyl xanthate can be produced more efficiently by recycling of the plant mother liquor [60]. Higher reaction yields of potassium amyl xanthate can be obtained by removing part of the water formed with pervaporation membranes [61].

Production in solvents is carried out either in an excess of the corresponding alcohol [62] or in an inert solvent such as petroleum ether [63]. The precipitated or crystallized xanthate is separated by filtration, washed, and dried. The continuous production of xanthates using aqueous alkali-metal hydroxide, an alcohol, and carbon disulfide has also been reported [64]. Moreover, reaction in aqueous solution is used to produce alkali xanthates in the presence of additives, giving dust-free, noncaking, hydrophobic powders [65].

Safety Aspects. The low flash point and ignition temperature and the toxicity of carbon disulfide require appropriate safety measures for the production plants. Dusting of xanthate powders can be prevented by additives [65] or by shaping processes [66].

5. Quality Specifications

The commercially available xanthates from C_2-C_6 alcohols are of technical grade only and usually 90 – 95 % pure. Another publication reports commercial xanthates to be rarely more than 90 % and frequently only 60 – 90 % pure [67]. The content of inorganic byproducts in technical xanthates varies, depending on their exposure to air [68]. Thus, alkali-metal sulfide, sulfate, trithiocarbonate, thiosulfate, or sulfite may be present. In addition, xanthates may contain some residual alcohol or alkali hydroxide. No general specifications for xanthates exist. They can be obtained as powder, granules, flakes, or sticks, and are also available in solution.

6. Storage and Transportation

Xanthates are usually transported and stored in steel drums. Copper, brass, zinc, and similar metals are not suitable. Aqueous xanthate solutions can be transported in vessels made from steel, steel alloys, or plastics, e.g., poly(vinyl chloride) or polyethylene. If the drums are kept cool and dry, solid xanthates are stable for years, but they may ignite spontaneously upon combined action of moisture and warming. Xanthate solutions may form carbon disulfide.

According to GeStoffV xanthates must be labeled as substances that are hazardous to health.

7. Analysis

Xanthates can be analytically determined by different methods [7]. Since many of the published analytical procedures have certain sources of error, the method of assay should be noted together with the specification of the xanthate content.

In general, the xanthate content is determined by a procedure based on decomposition of the xanthate with an excess of acid and subsequent back-titration with a base [3, 69].

Solutions of technical xanthates are usually assayed by *UV spectrometry.* This technique is also used for monitoring the concentration of xanthates in industrial flotation circuits [70]. Furthermore, xanthate solutions can be analyzed *potentiometrically* with silver nitrate [71].

Xanthates of $C_1 - C_5$ alcohols have been separated successfully by *chromatographic methods* such as thin-layer chromatography or HPLC [72].

8. Uses

Cellulose xanthates are the most important xanthates. They are used as starting material in the manufacture of cellophane (→ Films, Chap. 6.1.1.) and viscose fibers (→ Cellulose, Chap. 3.1.).

Flotation Reagents. The principal use for alkali-metal xanthates is as flotation collectors for metal-sulfide ores. Since their introduction in flotation in 1925 many patents and articles dealing with this field of application have been published.

Other applications of xanthates are only of minor importance. A selection of publications on the use of xanthates, drawn mainly from the extensive patent literature, is given below.

Polymerization. Xanthate derivatives are employed in polymerization processes as regulators [73], photoinitiators [74], and for the synthesis of block and graft copolymers [75]. Cyclic dithiocarbonate derivatives are suitable as cross-linking agents [76].

Additives for Lubricating Oils. Various dialkyl xanthates are claimed to be active as additives for lubricating oils [25, 77]. Moreover, xanthate complexes of molybdenum and vanadium are suitable as lubricant additives [78].

Color Photography. Xanthate derivatives are used in the preparation of electrophotographic material [79], as color developer, and photographic couplers [80].

Pesticides and Agricultural Chemicals. Xanthates and their derivatives have been recommended as fungicides [81], acaricides [82], and insecticides [83]. Microbicidal activity is also described for xanthate derivatives of benzeneacetic acid [84] and for quaternary ammonium salts [85] and *N*-methylpyrroles [86] containing dithiocarbonate residues. Halonitroaryl esters of *O*-butylxanthic acid exhibit nematocidal activity [87].

Other xanthate compounds effective as plant growth regulators are derivatives of dipropylene or triethylene glycol [88] and 3-benzothiazoline [89]. Various xanthate derivatives are claimed to be active as herbicides [90].

Pharmaceuticals. Pharmaceutical effects of xanthates include virustatic [91], antihypertensive [92], anthelmintic [93], analgetic and antipyretic [94], and antibiotic activity [95]. Pharmacological uses are also claimed for xanthate derivatives of aminoalkyl glycerols [96]. Potassium and gallium ethyl xanthate are effective antitumor agents [97] and 1,3-benzoxathiol-2-thiones (cyclic dithiocarbonates) can be used for treatment of liver diseases [98]. A number of phenylacyl xanthate esters and xanthogen formates (mixed anhydrosulfides) have been synthesized as potential radiosensitizers [99]. In addition, xanthates have been described as valuable intermediates for the preparation of drugs [100].

Rubber. Xanthates are used as antioxidants and vulcanization accelerators for rubber [101].

Environmental Chemistry. Traces of heavy metals can be removed from wastewaters by precipitation with xanthates [102]. Similarly, silver can be recovered from spent fixing baths using xanthates [103]. Cadmium can be extracted from soil by complexation with long-chain alkyl xanthates [104]. The recovery of xanthates from production mother liquors has been described [105].

Analytics. DNA suitable for polymerase chain reactions is isolated from plants, yeast, and bacteria using potassium or sodium ethyl xanthate [106]. Xanthates are also useful chelating reagents for the spectrophotometric detection of metals [107].

Other Uses. Substituted noble-metal xanthates are used in catalysts systems for removing impurities, e.g., S and N compounds, from hydrocarbons by hydrotreating [108].

Alkoxycarbodithiochloroformates are suitable condensing reagents in peptide synthesis [109].

9. Economic Aspects [110]

Various xanthates are produced by a large number of companies worldwide. The major mining chemical companies producing xanthates in Northern America are American Cyanamid, C-I-L (a wholly owned subsidiary of ICI), Kerley Enterprises, and Minerec Mining Chemicals. The Charles Tennant Co. plans (1993) to build a 12 000 – 14 000 t/a xanthate facility in Montreal, Canada. UCB in Belgium is the principal supplier of xanthates in Western Europe, but also sells to Africa, Canada, and the Philippines. Other producers in Western Europe are Hoechst (Germany), Shell (United Kingdom), and General Quimica (Spain). Robinson Brothers (United Kingdom) produces diisopropylxanthogen disulfide and zinc isopropylxanthate as rubber processing chemicals. Industrias Quimicas (Mexico), owned by Rhône-Poulenc (France), dominates the large Mexican market for xanthates and also sells to other South and Central American countries. Shell Chemicals produces xanthates and xanthogen formates in Chile. Karbochem (Republic of South Africa) manufactures a range of alkali-metal xanthates, marketing them in the Republic of South Africa and other African nations.

In 1989 prices for technical grade xanthates were in the range of $ 1.20 – 3.60 per kilogram for potassium amyl xanthate and $ 1.00 – 2.54 per kilogram for sodium isopropyl xanthate.

10. Toxicology and Occupational Health [111]

Data on the toxicity of xanthates and their derivatives in the literature are rather rare.

The alkali-metal xanthates are moderately toxic by ingestion or inhalation, but poisonous by intravenous route, as indicated in Table 3. In the body, xanthates act similarly to carbon disulfide.

Table 3. Toxicity of potassium xanthates, $R-O-CS-S^-K^+$, to mice

	LD_{50}, mg/kg	
R	Oral	Intravenous
Ethyl	683	199
Isopropyl	583	
Butyl	465	158
Isobutyl	480	158
Isopentyl	480	158

Animal experiments on the *chronic toxicity* of potassium amyl xanthate revealed that liver damage occurred in dogs exposed to an aqueous aerosol of 23 mg/m^3.

Because of their basicity, prolonged contact of alkali-metal xanthates and their concentrated solutions with the skin and especially with the eyes must be avoided. Skin contact may cause dermatitis.

Xanthates emit toxic fumes of SO_x and metal oxide when heated to decomposition. In the preparation and handling of xanthate solutions the possible formation of carbon disulfide requires protection against fire and explosions.

1. Introduction

The benzene homologues of general formula C_8H_{10} are generally known as mixed xylenes. The mixture of isomers with a boiling point range of 135 – 145 °C mainly consists of the three isomeric dimethylbenzenes and ethylbenzene:

o-Xylene *m*-Xylene *p*-Xylene Ethylbenzene

With the exception of xylene production by disproportionation of toluene, the isomeric xylenes and ethylbenzene are always produced as a mixture in all production processes. However, the relative proportions of the C_8 isomers often differ considerably (see Chap. 3).

Because of their high knock resistance (see Chap. 2), xylenes are well suited to the production of motor fuels. In terms of quantity the production of gasoline exceeds that of BTX aromatics (B = benzene, T = toluene, X = xylenes) quite considerably (in Western Europe in 1995 gasoline production was ca. 150×10^6 t and that of BTX aromatics ca. 13.7×10^6 t, of which ca. 2.7×10^6 t/a was mixed xylenes, 0.65×10^6 t/a *o*-xylene, and 1.4×10^6 t/a *p*-xylene) [1]. The average aromatics content of motor fuels in Western Europe is ca. 38 % [2].

The close association with gasoline production strongly affects the economics of separating xylene mixtures, for example, for use in chemical processes.

In Western Europe the production/use balance in 1995 was as follows [3]:

Production		
from coal	36×10^3 t	(ca. 1.3 %)
from pyrolysis gasoline	300×10^3 t	(ca. 11.1 %)
from reformate	2165×10^3 t	(ca. 80.0 %)
by disproportionation	205×10^3 t	(ca. 7.6 %)
Total production	2706×10^3 t	
Use		
in extraction and chemical processing (incl. imports)	2563×10^3 t	(ca. 88.4 %)
solvents	306×10^3 t	(ca. 10.6 %)
as gasoline component	30×10^3 t	(ca. 1 %)
Total use	2899×10^3 t	
Domestic production	93.3 %	
Net impor	6.7 %	

The structure of world mixed-xylenes production capacity in 1994 was as follows:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_433

Total capacity	23×10^6 t
Reformer	83 %
Disproportionation	10 %
Pyrolysis gasoline	6 %
Coal	1 %

In Western Europe until the year 2000 a significant increase in the proportion of xylene used in gasoline production is predicted, because the growth in production of xylene-containing reformate may exceed its consumption in chemical processes. However, in other regions, such as the United States, the reduction and limitation of the content of aromatics, and thus of xylenes, in gasoline is being discussed (see also Chap. 2 and Section 5.2) [2,4].

The use of xylenes in chemical processes broke down as follows (data for Western Europe 1995) [1]:

p-Xylene	1761×10^3 t (68.7 %)
o-Xylene	650×10^3 t (25.4 %)
Ethylbenzene and miscellaneous	152×10^3 t (5.9 %)
Total	2563×10^3 t

The dominant importance of *p*-xylene can be seen from the relative proportions of the isolated xylene isomers. *p*-Xylene is mainly oxidized to terephthalic acid, which can be esterified to dimethyl terephthalate (precursor for polyesters). *o*-Xylene is oxidized to phthalic anhydride (precursor for plasticizers) and *m*-xylene to isophthalic acid (precursor for polyesters). Ethylbenzene is dehydrogenated to styrene, which is converted to polystyrene and other polymers [5].

History [6]. Xylene was first discovered in crude wood spirit in 1850 by Cahours. The name xylene was derived from the Greek word *xylon* (= wood). Xylene was detected in coal-tar in 1855 by Ritthausen and Church. In 1891 ethylbenzene was found in hard coal-tar by Noelting and Palmar, and Moschner carried out the first synthesis of pure ethylbenzene from ethylbenzenesulfonic acid.

Between 1865 and 1869 Ernst and Fittig found that the "xylene" in coal-tar does not consist of a single compound. They synthesized "xylene" from toluene and named it "methyltoluene." They then established that some properties of "methyltoluene" differed from those of coal-tar xylene, particularly with regard to the nitro compounds. Fittig et al. concluded that in synthetic "methyltoluene" (*p*-xylene) the second methyl group was in a different position from that in coal-tar xylene.

Glinser and Fittig described the production of methyltoluene in 1865. Fittig obtained a hydrocarbon by dry distillation of the calcium salt of mesitoic acid which resembled both known modifications of dimethylbenzene, ("xylene" and "methyltoluene") but was not completely identical to either. The new hydrocarbon was named "isoxylene" (*m*-xylene). This work elucidated the structures of *p*- and *m*-xylene and proved their occurrence in coal-tar.

In a further experiment Fittig identified *o*-xylene as the third isomer, which was discovered in coal-tar by Jacobson in 1877.

m- and *p*-xylene were initially separated on the basis of their different chemical reactivity. *m*-Xylene reacts with concentrated sulfuric acid. *m*-Xylene is then regenerated from the crystalline *m*-xylenesulfonic acid using superheated steam in the presence of sulfuric acid. The fraction unaffected by sulfonation is then reacted with oleum. The sulfonic acid that crystallizes is cleaved to give pure *p*-xylene.

For decades coke-oven tar and benzole were used as raw materials for production of aromatics. Worldwide their production was associated in location and quantity with coal and steel production. The plants for extraction and refining of coke-oven benzole, a mixture of light oil from coke-oven tar and crude benzene, obtained from coke-oven gas by oil scrubbing, were built adjacent to coking plants. These plants were very small compared with those currently in operation. At that time the refining of crude benzole was carried out exclusively by washing with concentrated sulfuric acid, whereby impurities, such as resin-forming compounds, nitrogen and oxygen compounds, and some of the sulfur compounds, were removed as acid tar. However, valuable substances, such as styrene, were also lost in the acid tar. The xylenes were in demand as solvents and were used as raw materials in the chemical and pharmaceutical industries. However, production of the three isomers in pure form was complicated due to their almost identical physical properties. The quantities available were too small for the development of industrial xylene chemistry.

m- and *p*-xylene could be separated from *o*-xylene by distillation and thus *o*-xylene could

be obtained in limited purity. *m*- and *p*-xylene, however, could only be separated laboriously on the basis of their different chemical properties.

With the development of the hydrogenative refining of coke-oven benzole over sulfur-resistant catalysts under pressure, sulfuric acid refining became uneconomical and was replaced by a technically superior process (see → Benzene, Chap. 6.1.). Parallel to this development in process technology, aromatics production became independent of steelworks or coking plants and centralization took place. Large refineries and distillation plants provided a basis for modest chemical processing of the C_8 aromatics in the mid-1950s. Between 1955 and 1960 ca. 30 000 t of xylenes were obtained from a coke production level of $(40-45)\times 10^6$ t/a.

The fourth isomer, ethylbenzene, must be considered separately from the historical development of the isomeric xylenes. Its synthesis from benzene and ethylene in a Friedel – Crafts reaction solved the problem of raw materials at an early stage.

With the discovery of the catalytic dehydrogenation of naphthenes and the catalytic dehydrocyclization of paraffins and isoparaffins on noble metal catalysts and their bifunctional systems (platforming and rheniforming processes), the raw material basis for the development of xylene chemistry on a large scale was secured in Europe from about 1960. A large number of processes have now been developed: liquid – liquid extraction, azeotropic distillation, extractive distillation, isomerization, crystallization, adsorption, and absorption. These not only provided pure products on an industrial scale, but also permitted the separation of *m*- and *p*-xylene. Thus the basis for a large-scale growth of polyester fiber production was created. The residual *m*-xylene could be isomerized or oxidized to isophthalic acid, which had a limited market. The market for *o*-xylene was provided by phthalic anhydride production.

2. Properties [6]

Physical Properties. Technical-grade xylene is a mixtrue of C_8 aromatics, also known as the A_8 fraction, consisting of the three xylene isomers, ethylbenzene, and depending on the origin, varying amounts of nonaromatics which boil in the same range (136 – 145 °C). Table 1 lists some physical data for the aromatic components. Other data can be found in [7, 8]. The relative proportions of these components in a xylene fraction depend on its origin and also which process steps the xylene has already passed through (e.g., hydrogenation).

The vapor pressure curves of the three xylene isomers and ethylbenzene are shown in Figure 1.

The isomeric xylenes and ethylbenzene form azeotropic mixtures with water and numerous organic compounds (Table 2) [9–13].

The absorption properties of xylene are of technical interest because of the significant differences in the solubilities of various gases as a function of temperature (see Table 3).

Chemical Properties. Oxidation of the xylene isomers gives the corresponding aromatic dicarboxylic acids. Phthalic acid is produced industrially from *o*-xylene, isophthalic acid from *m*-xylene, and terephthalic acid from *p*-xylene (see → Phthalic Acid and Derivatives, → Terephthalic Acid, Dimethyl Terephthalate, and Isophthalic Acid).

The oxidation reactions have been established as industrial processes in both the gas and liquid phases. Attempts have been made to introduce the co-oxidation of *p*-xylene with paraformaldehyde (Toray Industries) or acetaldehyde (Eastman Kodak) [5].

Ammonoxidation of *m*- and *p*-xylenes initially gives the corresponding phthalic acid dinitriles, which are important raw materials for the production of isocyanates via reduction to the corresponding xylylenediamines. The dinitriles can also be hydrolyzed to the corresponding phthalic acids. However, this step has only limited industrial and economic importance.

The nitration of *o*- and *m*-xylenes provides a route to xylidines following hydrogenation of the initially formed dimethylnitrobenzene isomers. Xylidines are used as intermediates in dye and rubber additive production, for example (→ Xylidines, Chap. 6.1.).

The capacity of the xylene isomers to undergo isomerization and disproportionation reactions is also exploited industrially (see Chap. 4).

Sulfonation of *m*-xylene and subsequent decomposition of the sulfonic acid derivatives gives 3,5- and 2,4-xylenols, providing starting materials for insecticides, herbicides, etc.

Of the chemical properties of ethylbenzene as a component of the A_8 fraction, the most important is catalytic dehydrogenation to styrene, although ethylbenzene used for this purpose mainly comes from other sources (alkylation of benzene with ethylene).

Properties as a Motor Fuel Component. The properties of motor fuels are determined by a large number of quality aspects whose minimum requirements are mostly specified (see → Automotive Fuels). The value which is attributed to xylenes in blending of motor fuels essentially depends on how the xylenes can be combined individually with other available fuel components to produce motor fuel qualities which conform to market requirements. Typically the high knock rating, particularly as a blend component, and the low vapor pressure of xylenes are important factors affecting their use as motor fuel components. Table 4 compares the octane number and vapor pressure values (RVP) of the xylene isomers [14, 15] with the specification of a typical gasoline.

A more detailed account of the overall much more complex interactions with the pool of gasoline components can be found in Section 5.1.

3. Occurrence and Raw Materials

3.1. Natural Occurrence

Practically the only natural source of xylenes is petroleum. The concentration of xylenes varies considerably depending on location and geological age of the crude oil. Table 5 shows a comparison of the C_8 aromatics and the $C_6 - C_8$ aromatics contents in various types of crude oil [16].

Although in a few cases petroleums (e.g., that of South East Asian origin) can have an even higher aromatics content (up to 35 %), the direct isolation of xylenes is not economical.

3.2. Raw Materials for Xylene Production

For the industrial extraction of xylenes, the oil fraction or coal used as the raw material is subjected to thermal or catalytic treatment in which aromatics- and xylene-containing fractions are obtained. These conversion processes determine the quantity of xylenes available and supply them in a form that is enriched sufficiently to make isolation and further processing economical.

Raw Materials based on Petroleum.

Reformates. Xylenes are mainly isolated from reformates [17]. Naphtha fractions are used as the raw materials for the reforming process, which is now practically only carried out catalytically. Because of the sulfur sensitivity of the Pt – Re catalysts, the naphtha must first be desulfurized. The composition of the reformates and thus the xylene content depends on how the reforming process is carried out (see Section 4.1) and on the quality of the naphtha fraction used. The composition of the naphtha fraction, in particular its naphthene and aromatics content, significantly affects the composition of the reformate [18].

Naphthenic crude oils give naphtha fractions which are particularly suitable for reforming and aromatics production. However, naphtha fractions produced by hydrocracking (see → Oil Refining, Chap. 3.5.) also generally have high naphthene contents [19] and are therefore suitable starting materials for xylene production by reforming. Besides the composition, the boiling range of the naphtha fraction affects the yield of xylenes (see Table 6). A particularly high yield can be obtained when the naphtha fraction already has a high proportion of the corresponding xylene precursors (e.g., C_8 aromatics or C_8 naphthenes) in a suitable boiling range [20].

Pyrolysis Gasoline. The yield of pyrolysis gasoline and its xylene content is decisively affected by the raw materials used, and by the mode of operation of the plant (see Chap. 4). In steam cracking very different types of raw material can be used, which give rise to widely varying yields and compositions of the pyrolysis gasoline (Table 7) [21].

Only on using higher boiling hydrocarbons feedstocks can appreciable xylene yields and concentrations in pyrolysis gasoline be attained. Therefore, in general, isolation of xylenes is only economical when using these types of raw materials.

Raw Materials based on Coal. The isolation of xylenes from coke-oven tar, coke-oven benzole, or from hydrocarbon mixtures produced by hydrogenation of coal is of minor importance [17] (see also Section 4.1). The effect of the composition of the coal is described in [22]. Processes in which xylene-rich aromatics fractions can be produced from LPG or methanol are described in Chapter 4.

Table 6. Dependence of reformate composition on the boiling range of reformer feedstock (Kuwaitnaphtha) [20]

4. Production, Separation, and Further Processing

4.1. Production of C_8 Aromatics

Catalytic Reforming. Besides the nature of the raw materials, process engineering parameters also significantly determine the composition of the reformate and its content of C_8 aromatics [23]. The design of the catalytic reformer (see → Oil Refining, Chap. 3.4.) [24], its mode of operation, and the catalyst used are also very important. The three following types of catalytic reformer are in common use:

1) Semiregenerative reformer, in which the noble metal catalyst is periodically regenerated during a production shutdown (typically every 6 to 12 months)
2) Fully regenerative reformer, in which installation of an additional swing reactor allows the alternating regeneration of one reactor while the other continues to operate
3) Continuously regenerative reformer whose fluidized bed catalyst is continuously regenerated during operation

Operating conditions of the different types of reformer are listed in Table 8 [25].

Since at least six reactions take place in parallel during the reforming process, of which essentially only two lead directly to the formation of aromatics, establishing optimal operation conditions is very important. The reactions which give aromatics (the dehydrogenation of naphthenes and the dehydrocyclization of paraffins) are favored by comparatively high reactor temperatures and low pressures (see Fig. 2). At the same time a simultaneous increase in undesired side reactions (hydrocracking and coke formation) must be reckoned with, so that while increasing the severity leads to an increase in the aromatics content of the reformate, it also decreases reformate yield [26]. Dealkylation reactions are also of specific importance for xylene production. They can lead to decomposition of the xylenes formed, giving toluene, or benzene and methane, particularly at high temperatures.

A further control parameter for xylene production is the space velocity (LHSV). If throughput is lowered to increase the residence time in the reactor, reformates with high aromatics and xylene contents can be produced [25]. The adjustment of the operating parameters to give a maximum aromatics concentration in the reformate is known as aromizing. Within certain limits the quality of the reformate can also be in-

Table 8. Typical operating conditions of various reformer types [25]

Parameter	Semiregenerative reformer	Fully regenerative reformer	Continuously regenerative reformer
Pressure, MPa	1.5 – 2.5	0.7 – 1.5	1
Operating temperature, °C	510 – 540	510 – 540	510 – 540
LHSV ∗, h^{-1}	2 – 3.5	3.5 – 4	1.5 – 4

∗ Liquid hourly space velocity.

fluenced by the choice of catalyst. Besides conventional catalysts, which essentially only contain Pt as the active substances, bimetallic and multimetallic catalyst systems, additionally containing Re, Ge, Ir, or Pb, are used. For aromatics production the selectivity for C_{6+} aromatics is of general importance, while the suppression of dealkylation reactions is particularly important for xylene production. The activity of the catalyst can be increased by regular addition of chlorinated hydrocarbons. Major suppliers of reforming catalysts designed for xylene production include Acreon, Criterion, Exxon, Kataleuna, and UOP [27].

Figure 2. Variation of the selectivity of aromatics production in catalytic reforming with operating pressure

Steam Cracking. In contrast to the reforming process, the xylenes in the pyrolysis gasoline produced by steam cracking are regarded as byproducts of ethylene and propene production. However, their isolation can improve the economics of the process under certain circumstances. Although the operating conditions are not adjusted to maximize the xylene yield in steam cracking, the effect of severity on xylene formation is significant. Increasing the severity – i.e., raising the reaction temperature, lowering the residence time, and reducing the partial pressure by increasing the quantity of steam – significantly decreases the yield of pyrolysis gasoline [28], but increases the concentration of xylene (see Table 9) [29].

Synthesis Processes. In the Cyclar process developed by UOP/BP, propane and butane are converted into aromatics-rich gasoline fractions by cyclization over zeolite catalysts [30, 31]. On using propane the gasoline fraction contains ca. 17.3 wt % C_8 aromatics, and with butane ca. 19.8 wt %. The xylene yield is ca. 15 wt % based on the total starting material. A pilot plant for the Cyclar process has been commissioned at the BP refinery at Grangemouth, Scotland. For economic reasons, however, this process has not been put into industrial-scale operation. The same applies to the Mobil Oil process for synthesizing aromatics from alcohols using ZSM5 catalysts [31].

4.2. Separation and Further Processing

4.2.1. Separation of the C_8 Aromatics Fraction

The reformates used to produce C_8 aromatics can be processed such that C_8 and heavier aromatics are produced in the following approximate proportions [31]:

Benzene	13.2 %
p-Xylene	16.5 %
o-Xylene	8.3 %
C_{9+} aromatics	0.9 %

Besides the 38 % aromatics, 51 – 52 % naphtha fractions and 10 – 11 % gaseous products (hydrogen, fuel gases, etc.) are formed. This optimized result involves the following operations:

1) Toluene is dealkylated to benzene.
2) *m*-Xylene is isomerized to *o*- and *p*-xylenes.
3) Ethylbenzene is transalkylated to xylenes.

Table 9. Influence of severity in steam cracking on the yield and composition of pyrolysis gasoline (naphtha feedstock) [28]

Severity (% Ethylene)	Xylene + ethylbenzene (all products), wt %	Xylene + ethylbenzene in pyrolysis gasoline, wt %	Pyrolysis benzene yield, wt %
Low (24.4)	0.9	3.5	24.9
Medium (28.5)	1.6	7.2	22.6
High (33.4)	1.7	10.7	16.3

Figure 3. Flow sheet of the ethylbenzene distillation
a) Pre-column; b) Ethylbenzene columns

If the toluene is subjected to transalkylation instead of thermal dealkylation, the yield of xylenes can be further increased at the expense of benzene. The structure of a modern aromatics complex, which produces *o*- and *p*-xylene in the highest possible yield, is based on a combination of a series of these processes.

The ethylbenzene is mainly converted to xylenes because obtaining ethylbenzene from reformate is energy intensive. The main source of ethylbenzene, which is almost exclusively dehydrogenated to styrene, is therefore now the more economical alkylation of benzene with ethylene (see → Ethylbenzene).

Distillative removal of ethylbenzene, which for styrene production must be toluene-free, from reformates can take place after removal of toluene from the sump of the toluene column. Figure 3 shows a flow sheet of the ethylbenzene distillation. Other products obtained by this separation are the xylene and C_9 aromatics. The major separation problem is caused by a boiling point difference of only 2 °C between ethylbenzene and *p*-xylene. The distillative separation of this mixture requires high reflux ratios (1 : 80 to 1 : 120) with 300 – 360 effective plates. A yield of ca. 95 % ethylbenzene with > 99.5 wt % purity is achieved under these conditions [32].

Figure 4. Flow sheet showing separation of *o*-xylene
a) Xylene splitter; b) *o*-Xylene column

The distillative separation of *o*-xylene from the C_{8+} stream is also difficult. Although the boiling point difference is only ca. 5 °C, the required *o*-xylene purity (min. 98 %) can be achieved with 120 – 150 effective plates and a reflux ratio of 1 : 10 to 1 : 15, with a yield of > 95 %. Figure 4 shows a flow sheet for this separation. A further increase in *o*-xylene purity can be achieved by subsequent extractive distillation. Another method of separation is crystallization, mainly used to obtain *p*-xylene. This process utilizes the crystallization behavior of *p*-xylene near the eutectic point of a C_8 aromatics mixture. Depending on the composition of the mixture, this lies between −60 and −68 °C (see Fig. 5).

Figure 5. Melting behavior of the C_8 aromatics in their mixtures

Figure 6. *p*-Xylene crystallization by indirect refrigeration
a) Drier; b) Precooler; c) Scraped-surface crystallizer; d) Refrigeration plant; e) Filter; f) Centrifuge; g) Mixer

The Krupp – Koppers process (Fig. 6) is a typical example of the crystallization process. The actual separation process is a fractional crystallization in which the product of the first separation step in the filter (ca. 65 % of the *p*-xylene from the starting mixture) is mixed with highly concentrated *p*-xylene and is isolated in high purity in a centrifuge. This process and that of Phillips Petroleum [33] operate using indirect refrigeration.

Direct contact refrigeration involves downward flow of the initially cooled liquid in the vertical crystallization vessel. This in turn directly cools the remainder of the contents of the vessel (see Fig. 7).

Figure 7. *p*-Xylene crystallization by direct contact refrigeration
a) Drying; b) Crystallization; c) Centrifuge; d) Melting tank; e) Desorber; f) Scraped-surface crystallizer; g) Mixing tank

The cooling agent can be evaporating ethylene (Maruzen Oil Co.) [34]. Chevron Research and Development Corp., Sohio/BP, and Arco Technology use other process designs [35].

In the Parex process (UOP) [36] *p*-xylene is obtained in high purity from the isomer mixture by adsorption on a molecular sieve. The attached finishing column removes lighter components (raffinate consisting of ethylbenzene and a xylene mixture low in *p*-xylene) at the head. The *p*-xylene constitutes the bottom product of this column. Adsorption – desorption on the solid bed is carried out in such a way that a moving bed is simulated (Fig. 8). The rotary valve brings segments of the filled adsorption chamber into contact with the feed and with the desorbent in such a way that part of the molecular sieve adsorbs while another part is desorbed. The rotary valve switches the streams in the direction of flow in the bed. This simulates the movement of the adsorbent in a direction opposite to that of the liquid. The adsorbent exhibits high selectivity towards *p*-xylene compared with the other C_8 aromatics, especially ethylbenzene. Ethylbenzene is therefore one of the most suitable desorbents or eluents; this is kept in circulation in the extract column. The heavy part of the raffinate can also be used as the desorbent. The nonadsorbed C_8 aromatics leave the raffinate column at the head

Figure 8. Parex process
a) Adsorbent chamber; b) Rotary valve; c) Extract column; d) Raffinate column

and are then subjected to isomerization (Section 4.2.2).

The Parex process is a variant of the Sorbex group of processes. The first process which used this principle of the simulated moving bed was the Molex process developed in 1964 for the separation of *n*-paraffins from isoparaffins and cyclic hydrocarbons. Other modifications of the Sorbex processes are used to separate olefins and paraffins in $C_3 - C_{18}$ hydrocarbon mixtures (Olex process) and for separating carbohydrates (Sarex process).

4.2.2. Isomerization of the C_8 Fraction

The yield of *o*- and *p*-xylenes can be maximized by using catalytic conversion processes. The Isomar process (Fig. 9) [37] enriches the *p*-xylene in the Parex raffinate by re-establishment of the equilibrium. The acidic metal-containing zeolite catalyst used here also isomerizes ethylbenzene selectively to xylene isomers in their equilibrium ratio [38]. Since hydrogenolysis on the metal components must be guaranteed to maintain the activity of this bifunctional catalyst, the Isomar process is operated with a certain partial pressure of hydrogen in the catalytic reactor. Hydrogen is separated from the effluent from the Isomar reactor and then recycled together with fresh hydrogen. The liquid product is separated in a deheptanizer column. A C_7 stream is obtained at the head, which can be recycled to the starting reformate. The bottom product of this column is a *p*-xylene-enriched stream which, after clay treatment to remove unsaturated compounds is fed to the Parex unit to obtain the newly formed *p*-xylene.

Figure 9. Isomar process
a) Heater; b) Reaction column; c) Hydrogen separation; d) Recycle compressor; e) Deheptanizer column

In the Tatoray process (Fig. 10) toluene and the C_9 (A_9) bottom fractions from the A_9 column (*o*-xylene splitter column) are mainly converted into xylene isomers by disproportionation of the toluene and transalkylation of the C_9 aromatics (→ Toluene, Chap. 3.2.), affording a newly formed $A_6 - A_8$ fraction from A_{9+}. This technology is the product of cooperation between UOP and Toray Industries. Commercial applications have been in operation since 1978. Since then the catalyst has been improved sev-

eral times with regard to activity, thermal stability, and life span [37].

Figure 10. Tatoray process
a) Hydrogen recycle compressor; b) Catalytic reactor; c) Preheater; d) Hydrogen removal; e) Light ends removal; f) Clay tower

The Tatoray process consists of a reactor filled with solid catalyst to which are attached a cooling unit, a gas – liquid separation unit, a unit for distillation of the light components and one for clay treating to remove olefinic impurities. As in the Isomar process a partial pressure of hydrogen is maintained in the reactor. By processing different feed qualities, which can be influenced both by the different recycle rates and a varying charge of fresh reformate fractions, the composition of the product can be controlled.

Other proven disproportionation processes are the LTD process of Mobil Research of Arco Technology. Alkylation of toluene to increase the xylene yield has been developed by Mobil Chemical (Mobil toluene-to-*p*-xylene process = MTPX) and allows *p*-xylene concentrations of ca. 94 % to be achieved [39]. Mobil has announced that it will be using its new MTPX process in two facilities in the United States.

4.2.3. Combination of the Technologies in the Aromatics Complex

The maximization of the yields of *o*- and *p*-xylenes by combining isomerization, transalkylation, disproportionation, and adsorptive extraction of *p*-xylene is exemplified by the UOP technology complex (Fig. 11) [37]. In this complex all processes which are of industrial and commercial importance in this respect are represented. The center of the complex is the Parex process combined with Isomar technology. Tatoray technology is also used for conversion of the toluene and the C_{9+} aromatics fraction (A_9) [40].

Naphtha is used as the feedstock in this complex (cf. Fig. 12). It is obtained by conventional crude oil distillation, sometimes also from an evaporated BTX fraction. The reformer in this case is the UOP – CCR Platformer, which allows particularly high yields of aromatics to be obtained and also provides the hydrogen for subsequent processes, such as the Isomar and Tatoray processes, or for naphtha hydrogenation. The Sulfolane process is a frequently used liquid – liquid extraction, developed by Shell to obtain benzene and toluene from the reformate and from its $C_5 - C_7$-fraction (top product from the deheptanizer; see → Benzene; → Toluene, Chap. 3.). The bottom products from the reformate deheptanizer and from the toluene and post-Isomar deheptanizer columns are fed to the Parex unit. Consequently the products of the complex are *o*- and *p*-xylene, benzene, aromatics-free raffinate, and the C_{9+} aromatics.

5. Integration into Refinery and Petrochemical Complexes

5.1. Backward Integration into Petroleum Refining

Usually both the production and the separation and isomerization of the xylenes are integrated into refinery and petrochemical complexes [41, 42]. There are many advantages to this type of incorporation [43]:

1) Availability of a very favorable raw material base
2) Improved economics, especially in the use of byproduct streams unavoidably produced, such as pyrolysis gasoline or raffinates
3) Use of common infrastructure (energy, steam)
4) Possibilities for further processing of xylenes on site
5) Alternative use as fuel components if economical

Figure 14. Development of prices of naphtha and xylenes in Western Europe

Figure 15. Development of quantities of *o*- and *p*-xylene and primary downstream products produced in Western Europe

The integration of xylene production into the structure of a petrochemical refinery is shown schematically in Figure 12.

The separation of xylenes and other aromatics from reformate or pyrolysis gasoline frequently leaves a gap in the boiling curve of the motor fuels produced in the refinery. This phenomenon is typical of petrochemical refineries and is known as the gap fuel characteristic. To comply with motor fuel specifications it is sometimes necessary to add alternative fuel components in the same boiling range [44]. With regard to a possible future limitations on the total aromatics content of motor fuels, as is being discussed in the United States [4], the isolation of xylenes and other aromatics could, however, also help to fulfill the specification requirements [45].

5.2. Forward Integration into Chemical Processing

Apart from their use as solvents, the individual xylene isomers can be regarded as intermediates which are further processed in a series of reactions to give consumer products [5]. While immediate subsequent synthesis steps, such as oxidation of *o*- and *p*-xylenes to phthalic anhydride and terephthalic acid, can be integrated into petrochemical complexes to some extent,

further processing steps are mainly carried out at purely chemical sites.

The most important further processing steps and downstream products of the various xylene isomers and of ethylbenzene are shown schematically in Figure 13.

6. Economic Aspects

Parameters Affecting Economics. The economics of xylene production and isolation are essentially determined by two parameters [3]:

1) The price difference between the proceeds of xylene production and the cost of the naphtha used (see Fig. 14)
2) The value relative to that when used as a motor fuel component

The first aspect is the most important when targeted xylene production by reforming naphtha without the possibility of the alternative use in motor fuel is considered. However, the second aspect determines the economics of the separation of xylene mixtures, which can originate from reformate or pyrolysis gasoline, if the alternative option of use as a motor fuel component is available. Besides these aspects, other technical parameters, such as the performance of the reformer, the efficiency of the separating and isomerization plants, or the quality of the naphtha, affect the overall economics.

The naphtha/xylene price difference is also controlled by other, overriding factors. While the price of naphtha is closely linked to that of petroleum, the proceeds of xylene production are principally determined by the price and demand for downstream products.

From the historical and expected future development of the quantities of direct downstream products of *p*-xylene produced in Western Europe (see Fig. 15) [3], it may be deduced that conversion to purified terephthalic acid (PTA) will be increasingly favored over dimethyl terephthalate (DMT). On balance this leads to an increased overall demand for *p*-xylene which may essentially be attributed to the increasing demand for poly(ethylene terephthalate) resins for the production of plastic bottles.

In the past the primary downstream product of *o*-xylene, phthalic anhydride, was produced in significant quantities by oxidation of coal-tar naphthalene [3]. Now phthalic anhydride is mainly produced from *o*-xylene so the consumptions of these products are directly associated. They are only increasing slightly because of the relatively low growth rate of plasticizer production.

The main downstream product from ethylbenzene, styrene, is mainly converted to polystyrene and ABS elastomers. Correspondingly, the demand for these products determines the demand for ethylbenzene. Most of the ethylbenzene, however, is not produced within the framework of xylene production, but from benzene and ethylene [46].

The economic importance of *m*-xylene and its primary downstream product, isophthalic acid, is comparatively low. Regional demand for mixed xylenes in 1995 broke down as follows (total demand: 16×10^6 t):

Far East	44 %
North America	28 %
Western Europe	15 %
Eastern Europe	7 %
South America	3 %
Middle East	3 %

Producers. The most important producers and their production capacities for the various xylene isomers in Western Europe are listed in Table 10 [47]. Only in a few cases are additional capacities for conversion to phthalic anhydride or terephthalic acid and dimethyl terephthalate available at the same production site. The largest capacities for mixed xylenes are in North America and the Asia/Pacific region. Production capacities (in 10^3 t) worldwide for mixed xylenes follow [48]:

7. Quality Specifications and Analysis

Specifications for xylenes are generally laid by a particular company, depending on the intended application. Properties relevant to specification are determined by standard procedures [49].

Some important methods of determination for xylene follow:

1) Distillation range (e.g., DIN 51 761, ASTM D 850)
2) Hydrogen sulfide and sulfur dioxide content (e.g., ASTM D 853)
3) Thiol sulfur (e.g., DIN 51 765)
4) Density (e.g., DIN 51 757, ASTM D 891)
5) Flash point (e.g., DIN 51 755, ASTM D 56)
6) Color (e.g., ASTM D 156, ISO 6271)
7) Bromine consumption (e.g., DIN 51 774)
8) Purity/composition (e.g., ASTM D 1016; GLC determination)
9) Residue on evaporation (e.g., EN 5).

Typical specifications for *o*- and *p*-xylenes are given in Tables 11 and 12.

Table 11. Typical product specification for o-xylene

	Method	Value
o-Xylene (min.), wt %	GC	98.0
C_9 and higher aromatics (max.), wt %	GC	0.5
Nonaromatics (max.), wt %	GC	0.5
Density at 15 °C, kg/m^3	DIN 51 757	882 – 885
APHA color (max.)	ISO 6271	10
Copper corrosion (max.)	DIN 51 759	1
Hydrogen sulfide and sulfur dioxide (max.)	ASTM D 853	free of H_2S and SO_2
Acidity	DIN 51 558 T.1	not detectable
Start of boiling (min.), °C	DIN 51 761	143.0
End of boiling (max.), °C	DIN 51 761	145.0
Residue on evaporation (max.), mg/kg	EN 5	20

Table 12. Typical specification for p-xylene

	Method	Value
p-Xylene (min.), wt %	GC	99.4
C_8 aromatics (max.), wt %	GC	0.55
Other aromatics (max.), wt %	GC	0.05
Nonaromatics	GC	0
Density at 15 °C, kg/m^3	DIN 51 757	865 – 866
Copper corrosion (max.)	DIN 51 709	0
Total sulfur (max.), ppm	DIN 51 768	10 – 15
Acidity	DIN 51 558 T.1	not detectable
Distillation range, °C	DIN 51 761	1
mp, °C		13.1

The high purity requirement for *p*-xylene are due to the quality requirements for the production of pure terephthalic acid. Provided that further processing takes place via dimethyl terephthalate, sometimes somewhat lower degrees of purity can be tolerated. For *m*-xylene, which is produced in comparatively small quantities, only purities of 95.4 wt % min. are usually required.

8. Storage, Transport, and Safety

Instructions for ensuring safe storage, transfer, and transport of flammable liquids can be found in the technical rules for flammable liquids (TRbF), drawn up by the German committee for flammable liquids [50, 51]. For xylene the following TRbF numbers are important:

TRbF 001:	General, form, and application of the rules
TRbF 100:	General safety requirements
TRbF 111:	Filling stations, emptying stations
TRbF 112:	Gasoline stations
TRbF 120/121:	Tanks in a fixed location
TRbF 131/1 and 2:	Piping and tubing
TRbF 141:	Tanks on vehicles
TRbF 142:	Tank containers
TRbF 143:	Movable vessels
TRbF 180:	Operating instructions

The flammability limits for xylenes in air are between 1 and 8 %. Because the flash point of xylene mixtures is below 21 °C, they are mostly assigned to hazard class A I. The flash points of pure xylenes (not including ethylbenzene) are, however, > 21 °C so they may be declared as hazard class A II. For storage and transport xylenes must be labeled as readily flammable and harmful [51, 52]. For transport within Germany xylenes are assigned to class 3, cipher 31 c of the GGVS/GGVE regulations (regulations governing transport of hazardous goods by road and rail) [53].

9. Environmental Aspects and Toxicology

Environmental Aspects. In Germany xylenes are assigned to water hazard class 2 (WGK 2) [55]. The solubility of xylenes in water is low (ca. 0.14 g/L). Because of the comparatively low vapor pressure (7 – 8 mbar at 20 °C), the danger of vapor emissions in air is relatively low. However, xylenes can react with other air pollutants to give environmentally damaging products. This applies particularly to the UV-catalyzed photooxidation of xylenes by nitrogen oxides. However, compared with some other hydrocarbons, the reactivity of xylenes is comparatively low, with a reaction rate of ca. 2×10^{-9} min^{-1} [55]. For example, disubstituted internal olefins have a reaction rate of ca. 50×10^{-9} min^{-1}.

Toxicology. Exposure to xylene is possible through inhalation of vapors and resorption through the skin. The MAK value is 100 ppm (ca. 440 mg/m^3) for all three isomers [54].

General Activity. Xylene exhibits acute prenarcotic and narcotic activity. Chronic exposure to xylene leads to disturbance of the CNS (e.g., headaches, sleep disturbance) [56] and damage to the blood picture (dyspepsia). Provided that there is no long-term chronic overexposure, these effects are reversible. Besides developing a certain tolerance, frequent exposure to xylene can also lead to habituation or even addiction (solvent abuse).

Acute Toxicity. The LD_{50}, LC_{50}, and TCLo values for oral administration and inhalation vary widely, depending on the animal investigated and the isomer composition. The following values give an indication of the toxicity of xylene isomer mixtures [54, 57]: LD_{50} (rat, oral) 4300 mg/kg, LDL_0 (rat, i.p.) 2000 mg/kg, TCLo (humans, inhalation) 200 ppm.

A very high exposure to xylene of ca. 10 000 ppm caused by an accident led to lung edema and subsequent death in one person [58]. In other cases severe damage to the CNS, kidneys, and liver were observed.

Irritant Effects. On repeated application xylenes can cause irritation of the respiratory passages and mucous membranes of the eye. Frequent skin contact can lead to blister formation and dermatitis [57, 59–62].

Subchronic and Chronic Toxicity. At a concentration range of 100 to over 1000 ppm xylene in inhaled air, damage to the CNS with disturbance of balance or slowing of reactions is observed. Inhalation of xylene vapors can also cause nausea and headaches [63–65].

A change in the blood picture is also frequently observed. In ca. 10 % of persons who had been exposed to xylene vapors in concentrations of up to ca. 100 ppm for ca. 5 years, a leucocyte level of $< 4500\,\mathrm{mm}^{-3}$ was established [66]. A decrease in the immunobiological activity has occasionally been observed [58].

Carcinogenicity, Mutagenicity, and Embryotoxicity. The assessment of the carcinogenicity of xylenes is not consistent [67–69]. While in one study no indications of carcinogenicity or cocarcinogenicity were found, another investigation indicated that xylenes act as tumor promoters for skin tumors in rats.

None of the three xylene isomers showed mutagenicity in the Ames test [70]. However, slight mutagenicity was detected in a recessive lethal test on *drosophila* [71].

In animal experiments long-term exposure through inhalation of xylenes causes small changes to fetuses [72].

Pharmacokinetics and Metabolism. All three xylene isomers are resorbed in the same way. Various investigations have shown that ca. 60–70 % of the xylene reaching the organism via the lungs is retained [73–76]. This percentage remains approximately constant over the whole exposure period. The ratio of the concentration in the air in the alveoli ($\mathrm{mg/m^3}$) and in the blood (mg/kg) changes with the degree of bodily activity. When the body is at rest the ratio is ca. 15 : 1 and when moving ca. 30–40 : 1 [77]. Xylene can be resorbed at a rate of ca. 2.5 (0.7–4.3) $\mathrm{mg/m^3}$ per minute through intact skin [78].

Xylenes are deposited rapidly in body fat (up to ca. 5 %) and remain there for hours after exposure. The half-life in fat deposits is ca. 0.5–1.0 h [78]. The metabolism of the individual xylene isomers is identical. The main biotransformation pathway initially involves oxidation to methylbenzoic acid, which forms the corresponding methylhippuric acid by conjugation with glycine (A) [74, 79–81]. The methylhippuric acid can be excreted rapidly via the kidneys. Another, less favored biotransformation pathway involves the hydroxylation of the xylene on the aromatic ring, forming xylenols (B) [73].

1. Introduction

Xylidines are homologues of aniline and toluidine and are therefore very similar in chemical behavior.

Xylidines are used mainly in dye production. Their use in the production of vitamins, pharmaceuticals, and plant-protection agents is also important. Xylidine mixtures (crude xylidines), which were previously mixed with aircraft fuels in large quantities as antiknock agents, are still processed as antioxidants in lubricating oils and rubber products, e.g., car tires.

The xylidines **1**–**6**, $C_8H_{11}N$, molecular mass 121.18, are derived from the three isomeric xylenes:

2. Physical Properties

Xylidines are readily soluble in most organic solvents, but are not very soluble in water. At room temperature, xylidines are colorless liquids or congealed melts, each with its characteristic odor. Xylidines become colored within hours in light and air. Physical properties of xylidines are listed in Table 1.

3. Chemical Properties

Like aniline, xylidines are weak bases. The positions of the methyl groups have little influence on the basicity, which increases in the following order in aqueous media: **4** < **3** < **1** < **2** < **6** < **5** [1]. Xylidines form stable salts with strong mineral or organic acids. The differing solubilities of these salts can be used to separate isomers in some cases. However, this method is unimportant in industry [2].

Electrophilic substitution reactions on the aromatic nucleus, e.g., chlorination, sulfonation, nitration, nitrosation, or coupling with diazonium salts, take place very readily because of the high activation by the amino group and the two methyl groups. The positions *ortho* and *para* to the amino group are preferentially attacked. The amino group often needs to be protected. In strongly acidic media, the amino group is protonated and the ring is deactivated. In this case electrophilic substitution is directed to positions *meta* to the amino group [3].

The most important reactions of the amino group are acylation, alkylation, arylation, and diazotization. Xylidines can also be converted into the corresponding isocyanates [4].

4. Industrial Production

4.1. Reduction of Nitroxylenes

For all xylidines, apart from 3,5-xylidine and, to some extent, 2,6-xylidine, reduction of nitroxylenes is the most important industrial production route. The corresponding nitroxylenes can be obtained by nitration of the pure xylenes. If mixtures of isomers are obtained, as with *o*- and *m*-xylenes, the nitro compounds can be easily separated by rectification.

Crude xylidines, previously obtained in large quantities by nitration of xylene mixtures (crude xylene) and subsequent reduction, can be further processed to give the pure xylidines, but at great expense [5].

For the reduction of nitroxylenes, processes used in the production of aniline and toluidines can, in principle, be considered. The classical Béchamp reduction with iron and hydrochloric acid [6] has now been widely replaced by catalytic hydrogenation with molecular hydrogen. Usually continuous or batch processes in the liquid phase, generally without solvents, are used [7, 8]. If solvents are used, these are aromatic hydrocarbons, lower aliphatic alcohols, and acetic acid [9, 10]. Palladium on activated charcoal is the most important catalyst. Other possible catalyst systems are platinum or ruthenium on activated charcoal, aluminum oxide, or kieselguhr and Raney nickel [11].

In 1943 and 1944, xylidines were produced in the United States in large-scale industrial plants. Hydrogenation in the gas phase was mostly used [12, 13]. Nickel, nickel – copper, or sulfidic catalysts based on copper, nickel, chromium, molybdenum, or tungsten were used [14, 15].

4.2. Amination of Xylenols

3,5-Xylidine cannot be prepared at all by the nitration of *m*-xylene, as the corresponding 5-nitro-*m*-xylene is formed in $< 1\,\%$ yield . The production of 2-nitro-*m*-xylene, formed in 16 % yield in the nitration of *m*-xylene, depends on the market for 4-nitro-*m*-xylene. 2,6-Xylidine can therefore be produced by the nitration of *m*-xylene only to a limited extent. To produce both these xylidines, processes starting from the generally readily accessible xylenols are more suitable.

In the Halcon process, (also used for the production of aniline) xylenols can be converted to xylidines with excess ammonia at high pressure and temperature on aluminum-oxide-containing

catalysts [16, 17]; a disadvantage is that extensive dealkylations and isomerizations can occur, in particular when xylenols with *ortho* methyl groups or spent catalysts are used [18]. In the Ethyl Corporation process these disadvantages are avoided, if sterically hindered xylenols in the presence of catalytic quantities of a cyclohexanone are converted to xylidines with ammonia using a hydrogen transfer catalyst [19]. In another process developed by the same company, 2,6-xylenol can be aminated under anhydrous conditions via the aluminum salt [20].

4.3. Other Processes

3,4-Xylidine can be obtained by catalytic hydrogenation of 2-chloromethyl-4-nitrotoluene [21]. 3,4- and 3,5-Xylidines can be produced by amination of the corresponding substituted bromoxylenes under high pressure with a copper catalyst [22, 23].

Another process, which can be used to obtain 3,5-xylidine, is the reaction of α,β-unsaturated cyclohexenone oximes with dehydrating agents [24]. Ciba-Geigy describes the condensation of acrolein with the enamine from diethyl ketone and morpholine to give 2,6-dimethylcyclohexenone. The latter can be converted to 2,6-xylidine in a second step with ammonia in the presence of hydrogen-transfer catalysts using a method similar to that of Ethyl Corporation [25].

5. Quality Specifications, Storage, and Transport

Technically pure xylidines are rectified products, generally of purity $> 99\,\%$. The content can be determined simply by titration, GLC [26], or HPLC [27]. Other isomers and side products with hydrogenated aromatic nuclei can be present as impurities. To identify other impurities, e.g., hydroxylamines, azo and azoxy compounds, or phenols, TLC methods are suitable, particularly when these substances are present in trace amounts. The residual moisture is $< 0.1\,\%$ and is determined titrimetrically by the Karl Fischer method. In the case of crude xylidines, the isomer distribution should usually be specified. This can vary within wide limits, depending on the supplier.

The freshly distilled product is pale yellow. On storage over longer periods, particularly in the presence of light and air, and depending on the other storage conditions, the product increasingly becomes red with no detectable change in the xylidine content. The Hazen color index provides a measure of the coloration. The coloration can be suppressed for a certain period by addition of various stabilizers in quantities of $0.05 - 0.5\,\%$. (For the mode of action of structurally different stabilizers see [28].) The following are effective stabilizers: hydrazine hydrate [29], aliphatic polyamines [30], aromatic biguanides [31], alkylphenols [32], and sulfur-containing compounds [33].

Iron containers are used for storage and transport. Table 2 gives the hazard classes and registrations of the individual xylidines [34].

6. Use

6.1. Dye Production

A large number of azo dyes are derived from 2,4- and 2,5-xylidines, whereby the xylidines can function both as diazo and coupling components. Instead of pure 2,4-xylidines, crude xylidines are frequently used to produce red and orange acid dyes.

Yellow and orange solvent dyes and some red acid and direct dyes are produced from 2,4-xylidine. An example of an azo dye based on 2,5-xylidine is Solvent Red 26 (C.I. 26 120).

Of the three theoretically possible 2,4-xylidinesulfonic acids, two are important as diazo components in the production of azo dyes. 4-Amino-1,3-dimethylbenzene-6-sulfonic acid is formed by sulfonation of 2,4-xylidine with oleum [35], and is preferentially used for the production of acid azo dyes. Baking sulfonation of 2,4-xylidine gives 4-amino-1,3-dimethyl-5-sulfonic acid [35], which is further processed to give Acid Orange 9 (C.I. 17 925) and Direct Violet 7 (C.I. 27 855). The reaction of xylidines with diketene [36, 37] is an important first step in the production of pigment dyes. An interesting example of this class of compound is the 2,4-xylidide of acetoacetic acid, used principally as the coupling component for Pigment Yellow 13 (C.I. 21100).

3,5-Xylidine	1 [a]	707	[68,69]

[a] mg/plate.
[b] Mouse.

2,5-Xylidine is also used to produce triphenylmethane dyes, such as Solvent Yellow 30 (C.I. 21240), Solvent Red 22 (C.I. 21250), and Acid Red 65 (C.I. 24830).

3,5-Xylidines are currently almost exclusively used to produce the perylene pigment dye Pigment Red 149 (C.I. 71137). Only a few areas of use are known for 2,3-xylidine; e.g., in the form of the amide of 2-hydroxy-3-naphthoic acid, it is a coupling component for azo dyes used in printing inks.

The condensation product of bromamine acid with 2,6-xylidine is an intermediate in the production of acidic blue dyes for wool [38] and reactive dyes.

6.2. Plant Protection

2,3-Xylidine is a component of the herbicide xylachlor (Combat) [39]. The insecticide and acaricide amitraz is obtained from 2,4-xylidine.

5-Acetamido-2,4-dimethylaniline, which can be obtained by nitration and subsequent catalytic hydrogenation of *N*-acetyl-2,4-xylidine, is an intermediate in the production of the herbicide and growth regulator methafluoridamid, mefluidide (Embark, Vistar) [40]. Prowl (Pendimethalin, Penoxalin) is also used as a herbicide and growth regulator [41,42]; it is obtained from 3,4-xylidine by alkylation and dinitration.

2,6-Xylidine is an interesting precursor for a large number of plant-protection agents. Derivatives of *N*-chloroacetyl-2,6-xylidine are of interest as herbicides, growth regulators, and fungicides. Commercial products based on 2,6-xylidine are the fungicides metalaxyl (Ridomil) [43] and furalaxyl (Fongarid) [44].

6.3. Production of Pharmaceutical Products, Pharmaceutical Products for Veterinary Medicine, and Vitamins

The antiphlogistic, antirheumatic, and analgesic mefenamic acid is produced from 2,3-xylidines [45].

2,4-Xylidine is the starting material for the active substance cymiazole (Tifatol, Besuntol), used in veterinary medicine as an ectoparasiticide for combatting ticks [46,47]. 2,6-Xylidine is a component of a range of similarly structured local anesthetics, such as lidocaine, bupivacaine, mepivacaine, and etidocaine [48,49]. 2,6-Xylidine is also used in a range of other medicinal products, e.g., the diuretic xipamide [50], the amidinourea derivative lidamidine hydrochloride [51], which combats diarrhoea, the arylurea derivative xilobam, which has a tranquil-

izing effect on the central nervous system [52], and the coronary vasodilator lidoflazine [53]. The active substance xylazine hydrochloride (Rompun) is also produced from 2,6-xylidine [54], and is used in veterinary medicine as a narcotic and sedative.

3,4-Xylidine is used in the synthesis of riboflavin (vitamin B_2) [55]. It is also a precursor in the biosynthesis of vitamin B_{12} [56].

6.4. Other Uses

The use of xylidines as antiknock agents for gasoline [57] and as antioxidants for lubricating oils and rubber products [58, 59] has already been mentioned. Xylidines are still added to gasoline as coloring agents; 2,5-xylidine is used as an additive for liquid crystal mixtures [60]. The use of xylidines as corrosion inhibitors in metallic materials has also been described [61]. Xylidines can be used as absorption agents for sulfur dioxide in desulfurizing exhaust gas [62].

The reaction of formaldehyde with xylidines is analogous to that with aniline, and gives diaminotetramethyldiphenylmethanes [63] and, under hydrogenation conditions, diaminotetramethyldicyclohexylmethanes [64]. These products are used as cross-linking agents and hardeners for epoxy resins, or can be further processed to polyurethanes.

7. Toxicology

Xylidines are readily resorbed by the skin and mucous membranes. Their ability to bind hemoglobin is known, in good agreement with the established maximum methemoglobin level.

Detailed test have been carried out with 3,4-xylidine and 2,4-xylidine [65]. Very high xylidine concentrations attack the central nervous system directly. Xylidines also lead to induction of microsomal enzyme systems in the liver. In animal experiments, toxic effects on the lungs and kidneys have also been established.

All the isomers of xylidine are identified as mutagenic, 2,4-, 2,5-, and 2,6-xylidines have also been found to cause tumors. The LD_{50} (oral) for rats is 0.1 – 1 g. The MAK value has been set at 5 mg/kg for any single xylidine. Table 3 gives an overview of the toxicological data described.

There are reports of tests for carcinogenesis on 2,4-, 2,5-, and 2,6-xylidines, which have been found to cause tumors. High doses of 2,6-xylidine, which has been identified as a component of tobacco smoke, leads to adenomas and carcinomas in the nasal cavities in rats. Mesenchymal tumor and rhabdomysarcoma have been observed as malignant carcinomas. Subcutaneous tumors and neoplastic lumps in the liver have also been found. In rats 2,6-xylidine is classed as definitely carcinogenic [70].

1. Introduction [1]

The first records on the use of yeast date back to 6000 B.C. Egypt, where a type of acid beer called "boozah" was produced.

The production of wine, beer, and leavened bread probably developed over the next few thousand years. In Roman times, beer was a common drink in Spain and Germany. The British welcomed the production of beer by the Romans and adopted it as their national drink.

The people of South Asia have for thousands of years prepared and stored food by fermentation methods, e.g., rice wine, sugar cane wine, pickles, fish sauces, and various soy foods.

Many other foods, such as cultured dairy products, fermented sausages, etc., also contain microorganisms, including yeast. So, microbial cells have long been consumed by humans. Kaffir beer, for example, which is a traditional beverage in Africa, is still produced and is almost a complete diet due to its balance of yeast and grain. The nature of yeast long remained unknown until Pasteur established beyond doubt the role of yeast in the fermentation of sugar to alcohol, and that yeast is a living organism.

The technology of microbial cell production on a commerical scale for food and feed has developed only within the past 100 years. In ancient times people recovered top fermenting yeasts of the genus Saccharomyces from the production of fermented beverages such as beer, and used them as leavening agents in baked goods. Preparation of compressed brewer's yeast began in the late 1700s in Great Britain, The Netherlands, and Germany.

By 1868 Fleischmann had founded the compressed yeast industry in the United States and concurrent improvements in the biochemistry of fermentation and technical engineering greatly aided the development of the modern yeast factory. Continuous aeration and separation by centrifugation were developed for baker's yeast production.

Modern technology for microbial cell production dates from World War I. Large-scale fermenters with effective aeration were developed and new continuous processes were used. New raw materials (molasses, sulfite liquor, hydrocarbons, whey, starchy wastes from potato processing, date syrup, etc.) were used. The number of yeast strains and species grown on different raw materials also increased.

In the fermented foods and beverages industries, the growth and human consumption of microbes started in Germany in about 1910 with the brewer's yeast which was separated from beer, washed, and dried. During and following World War II *Candida utilis* yeast was grown on wood sugar containing sulfite liquors. Although the main usage of microbial biomass is at the present in feeds, good possibilities exist for the increase of food applications.

Four species of yeasts are presently used in foods: *Saccharomyces cerevisiae*, *Sac-*

charomyces uvarum (formerly *Saccharomyces carlsbergensis*), *Candida utilis* (*Torula utilis*), and *Kluyveromyces fragilis* (formerly *Saccharomyces fragilis*). *Saccharomyces cerevisiae* and *Saccharomyces uvarum*, the yeast of the brewing industry, are byproducts of beer production. Other yeasts are grown especially for food and feed use and are often called primary yeasts. *Torula utilis* is grown in sulfite liquor, and *Kluyveromyces fragilis* on cheese whey. Yeast may also be grown on hydrocarbons; however, this was found to be infeasible due to economic and safety reasons.

Detailed food analysis shows that yeast is a rich source of protein, essential minerals, and one of the richest sources of B group vitamins.

Although fermentation and leavening are the most common use of yeast in food production, the application of yeast and yeast derivatives for nutritional fortification (as protein and vitamin sources) of processed foods and also for refining their flavor profile is growing.

Industrially important yeasts include baker's yeast, brewer's yeast, wine yeasts, and distiller's yeasts. Yeast-derived products are numerous including flavors and flavor enhancers, nutritional yeast, colorants, and a broad spectrum of products of pharmaceutical and cosmetic value. From different yeasts, several enzymes and biologically active compounds are produced on a commercial scale such as alcohol dehydrogenase; hexokinase; L-lactate dehydrogenase; glucose-6-phosphate dehydrogenase; glyceraldehyde-3-phosphate dehydrogenase; inorganic phosphates; coenzyme-A; oxidized and reduced diphosphopyridine nucleotides; and mono-, di-, and triphosphates of adenine, cytidine, guanosine, and uridine.

It is difficult to precisely define yeast on the basis of general morphological and physiological considerations. For example, most yeast cells are colorless and transparent, while some produce carotenoid pigments (e.g., Rhodotorula). Bud formation is widespread, but is not common to all yeasts. Cell shape, in most cases, is round to oval, but several species of some genera may produce a true mycellium.

The taxonomy of yeasts is in a continual state of flux. As new microorganisms are discovered, increasing knowledge about them results in the yeasts being shifted within subgroups. However, such changes are slow to be put into practice, except by taxonomists.

Frequently, species were named on the basis of fermentation they were associated with, e.g., *Saccharomyces vinii* or *Saccharomyces* sake. The morphological and physiological properties are often very similar, and separate names have not been justified taxonomically. For various industrial processes, special characteristics of production strains are of great importance; therefore, strain differentiation may be more valuable than species classification.

2. The Yeast Cell

Electron micrographs of thin sections of yeast cells show the existence of a cell wall, a plasma membrane, nucleus, mitochondria, and vacuoles.

The cell wall makes up 15 % to 20 % of the dry weight of the cell. The proportional weight of the cell wall usually decreases during the growth phase and increases again in the stationary phase. The main cell wall components are the polysaccharides glucan and mannan, chitin, protein, and lipids. Acid hydrolysis of the cell wall results in the formation of glucose, mannose, glucosamine, amino acids, phosphates, and lipids. The chemical composition of the cell wall of *Saccharomyces cerevisiae* shows great variability, with carbohydrates varying from 60 to 91 %, proteins from 6 to 13 %, and lipids from 2 to 5.8 %. The two main polysaccharides are present in about equal amounts. Chitin is a polymer of β-(1 – 4)-linked *N*-acetylglucosamine.

The cell-wall protein contains all the common amino acids, with high proportions of glutamic and aspartic acids. In contrast to the whole-cell protein amino acid composition, cell-wall protein has a high content of sulfur amino acids which, especially in younger cells, contain SH groups. In older cells the protein chains are linked by disulfide bonds. The structural protein of the cell wall is mainly bound to polysaccharides to form a complex structure in which glucosamine acts as the connecting link between the polysaccharides and proteins.

The lipid content of the cell wall varies both with species of yeast and growth conditions. Published data show great variations, probably due to incomplete removal of the lipid-rich

plasma membrane. Some of the lipid content is firmly bound to the cell wall and may play a role in maintaining its orderly structure. $C_{16:1}$, $C_{18:1}$, and $C_{16:0}$ acids are the dominant fatty acids of the cell-wall lipids. The plasma membrane lipids have a higher content of $C_{18:1}$ acids; in addition the phosphatidylinositol and phosphatidylserine components of phospholipids are enriched compared to the cell.

The nuclei of yeast are surrounded by an envelope which is characterized by the presence of many pores.

Mitochondria are abundant in all fungi. Their most morphological characteristic is the presence of inner and outer membranes. The size, shape, number, and composition of mitochondria vary widely under different conditions of growth.

Vacuoles are important subcellular organelles in yeasts. Both vegetative and reproductive cells contain vacuoles that vary significantly in size. The vacuoles contain a variety of hydrolytic enzymes such as proteases, and occasionally they contain degrading intracellular substances.

3. Food and Feed Yeast [2]

Yeast-fermented foods constitute a significant percentage of the human diet. Nutritionally, the most important yeast fermentations are baked goods and beer. Yeasts also have some importance as foods and feeds.

About $(70-80)\times10^6$ kg of baker's yeast (dry basis) are produced annually in the United States. Most of this is used in the production of baked goods as compressed or active dry yeast. About $(2.3-4.6)\times10^6$ kg is used for direct consumption as dried nutritional yeast. In the brewing industry 2.3 – 3.6 kg of yeast (dry basis) become available as excess yeast per barrel of beer. Thus, the total supply is ca. 55×10^6 kg/a. Most of this yeast is used in feed, usually by co-drying it with spent grains, another byproduct of the brewing industry. But a considerable percentage, as much as 14×10^6 kg, is used in the production of yeast extracts or sold as debittered brewer's yeast for nutritional purposes.

In some fermentation industries the yeast cannot be recovered as such because the fermented grape must or the fermented grain mash contains insoluble particles that make separation of the yeast impractical. In the wine industry, the yeast is discarded with the lees. In the production of distilled beverages the yeast is co-dried with the distiller's solubles or the spent grain and used as feed. Active dry yeast is also used as a supplement to ruminant feeds and has been reported to increase feed efficiency in cattle.

Yeast flavor may be pleasant for some people or indifferent or less than desired to others. It is not used because of its flavor but because of its nutritional contribution of protein, vitamin B_1, and minerals. Yeasts are sold for human consumption as inactive dried yeasts. They are killed by pasteurization or during drum or spray drying. The dried powders or flakes are usually consumed by blending them with fruit juices or by sprinkling over cereals. In the health food industry yeasts are promoted on the basis of unidentified nutritional factors. Such claims have to be treated with considerable caution because of their promotional aspects. However, two such previously undefined nutritional factors that were discovered in yeasts in the 1950s are selenium and chromium, which are now recognized as essential trace elements.

3.1. Composition

The gross composition of yeasts is quite variable. The percentage of proteins and nucleic acids depend on the substrate and growth rate. Yeast composition is outlined here on the basis of *Saccharomyces cerevisiae*. The other two nutritional yeasts, namely *Candida utilis* and *Kluyveromyces marxianus*, have somewhat similar composition.

Protein. The protein of yeasts is usually determined by Kjeldahl nitrogen determination and multiplication of the nitrogen content by 6.25 ($N\times6.25$). The total nitrogen includes the nitrogen of the nucleic acids and, therefore, this procedure overestimates the protein content. Protein calculated in this manner should be designated crude protein. A factor of $N\times5.5$ is more appropriate to estimate pure protein.

General use of the 6.25 factor has led to underestimation of the nutritional value of yeast proteins expressed by the protein efficiency ratio (PER) because animal feeding tests were carried out at an assumed protein value higher than

the true value. Much of the literature uses a PER value of 1.8 (cf. casein PER of 2.5).

Total yeast proteins are generally higher in lysine and deficient in sulfur amino acids, methionine, cysteine, and cystine as compared to cell-wall protein amino acid composition (see Chap. 2). The amino acid composition of yeasts resembles that of oil-seed proteins, particularly soy protein.

Vitamins. Most yeast species are unable to synthesize one or more vitamins and are dependent on external sources.

Yeast contains predominantly the vitamins of the B complex, and is thus an excellent source of B vitamins for human and animal nutrition.

Inactive dry yeast is frequently used as a vitamin supplement rather than as a source of protein in food formulations. Some dry yeast products are even fortified with vitamins such as B_1, B_2, and niacin to meet certain special requirements of vitamin tablet manufacturers. Although the daily requirements for most of the B vitamins are not fully met by the recommended yeast intake, their contribution to meeting the B complex vitamin requirements in the human diet is substantial. However, yeast does not provide vitamin C and fat-soluble vitamins such as A, E, K, and D. Nevertheless, dry yeast can function as a valuable vitamin source when used in combination with other food ingredients, as is generally the case with human diets.

Baker's yeast contains 7 – 10 % ergosterol, mainly in the membranes. It serves as the precursor for vitamin D_2. This conversion occurs when ergosterol is irradiated with ultraviolet light. However, this process is not economical since synthetic vitamin D_2 is less expensive. Baker's yeast does not contain 7-dehydrocholesterol, the precursor of vitamin D_3.

Minerals. Yeasts take up substantial quantities of macro- and micronutrients from the surrounding growth medium. The mineral-ash content amounts to ca. 8 % on a dry solid basis. Although the concentrations of potassium and phosphorus in dry yeast are higher than those of other elements such as Ca, Mg, and S, the mineral contributions made by an allowable daily serving of 20 g of dry yeast is minor considering the high mineral content in the bulk of an average human diet.

However, nutritional studies have shown that certain diets are deficient in some important trace elements. Supplementation of these diets with dry yeast has partially or wholly alleviated such dietary problems. Such inadequacies in the diet were later determined to be due to deficiencies of trace elements such as chromium, selenium, and molybdenum. Brewer's and baker's yeasts contain these elements in trace levels. Specially produced yeast products are now commercially available with higher levels of these micronutrients.

Chromium. In 1955 researchers reported that rats fed with certain nutritionally deficient diets showed impaired tolerance to blood glucose. The conditions were then reversed by supplementing the feed with brewer's yeast. It was later suggested that the active component responsible for reversing the glucose intolerance was an organic complex rich in chromium.

Diabetes, which is caused by glucose intolerance, can manifest itself in two ways. In juvenile diabetics, the pancreas fails to secrete insulin into the bloodstream. Those who are affected by another type of glucose intolerance begin to show symptoms in midlife. These patients secrete insulin into the bloodstream but cannot control their blood sugar level. It is possible to correct this problem by supplementing the diet with brewer's yeast. Findings have indicated the importance of another component besides insulin for the proper control of the blood sugar level. This active component, which is a trivalent chromium complex, is now referred to as glucose tolerance factor (GTF). Patients in the second category have GTF early in life, but tend to lose it with age, causing increased vulnerability to diabetes. It is suggested that GTF functions as a cofactor for insulin, thereby enhancing the binding of insulin to receptive sites on the membranes of insulin-sensitive tissues.

Other investigations showed a reduction in the level of cholesterol and triglycerides in the blood of humans supplementing their diets with brewer's yeast rich in GTF. However, further feeding studies are necessary to confirm the results before yeast rich in GTF could be recommended as a possible treatment for lowering blood sugar or curing lipid disorders.

Selenium has been recognized as an essential trace element for both human and animal nutrition. Recent surveys in some parts of Fin-

land show that people with blood selenium less than 0.04 µg/L are three times more prone to heart attacks than their counterparts with normal selenium levels. Also, in China a fatal heart disease in children known as Kaishan's disease is presently treated by fortifying the diet with sodium selenite.

The importance of selenium in animal nutrition is also well documented. A common disease in lambs, white muscle disease, is due to selenium deficiency. It can be cured by adding 0.05 ppm Se to the diet.

A diet containing Se at the levels approaching toxicity is effective in lowering the incidence of some types of cancer in animals. Research findings strongly suggest that certain types of cancer can be prevented by maintaining a proper level of Se in the diet.

Early feeding studies conducted with selenite or selenate salts as sources of Se showed that the uptake of Se was quite poor. In contrast, organically bound Se, such as selenomethionine found in some natural foods, is incorporated several times faster into the body tissue than inorganic Se.

Organically bound Se is now recognized as nutritionally important because of its ability to prevent some vitamin E deficiency disorders, at least in laboratory animals fed diets partially reduced in nucleic acids.

Reports, particularly from Finland, indicate that Se deficiencies can be corrected by supplementation with Se-rich yeasts.

There are several factors that restrict Se uptake by yeast under conventional batch propagation conditions primarily because of toxic effects of Se salts on yeast growth. However, a new procedure for the propagation of food-grade Se-rich yeast has been developed, based on the concept that, under conditions of sulfur deficiency, sulfur could be replaced by selenium in yeast. The growth medium is fed incrementally so that the Se concentration never reaches toxic levels. Under these conditions the yeast assimilates Se as a reaction to sulfur deficiency. Nutritional yeasts with an intracellular Se concentration of 1000 ppm are commercially available in the United States as dietary supplements.

Lipids. The lipid content of yeasts can vary between 4 and 7 % (dry basis). About 1 % can be extracted directly by solvents. The determination of total lipids requires acid hydrolysis prior to solvent extraction. Major constituents are fatty acid glycerides with a predominance of palmitic and oleic acids, sterols, and lipolipids.

Carbohydrates. Total carbohydrates account for about 30 – 35 % of the yeast cell (dry basis). They consist mainly of carbohydrate storage compounds such as glycogen, the disaccharide trehalose, and the structural materials of the cell wall: the glucans and mannans. Level of fiber in whole baker's yeast cells is about 18 % (dry weight basis).

3.2. Use of Yeast as a Major Protein Source

Candida utilis yeast was used as an important human diet supplement in Germany during World War II. Sulfite waste liquor, a byproduct of the paper pulp industry, and wood hydrolysates were used as raw materials. The large-scale production of yeasts on hydrocarbon substrates was found to be infeasible for economic and safety reasons.

For use as a major source of protein by humans the presence of nucleic acid is a serious obstacle; nucleic acid nitrogen accounts for about 10 – 15 % of the total nitrogen of yeast cells. The intake of nucleic acid leads to elevated blood plasma levels of uric acid and may cause gout. Sources of nucleic acids in the diet are meat, particularly organ meat such as liver. Beer and possibly other fermented beverages also contain nucleic acids.

Search for methods is underway to reduce the level of nucleic acids or to remove them completely, since present methods are not economical. There is no need, however, for the removal of nucleic acids from yeast biomass for use in feed.

Yeast biomass in its inactive dried form is used widely as feed supplement. It is used in poultry rations and pig starter feeds. The use of brewer's and distiller's byproduct yeast in feed has been demonstrated. In countries that lack cheap sources of oil-seed meals (mainly soybean meal), *Candida utilis* biomass is used extensively as a protein supplement. Live yeast cells in the form of active dried yeast or yeast culture are also used in the feed industry.

Yeast culture is produced by combining slurries of baker's yeast with cereal feed grains. The mash is incubated to permit yeast multiplication and fermentation. It is then dried at temperatures that preserve yeast viability.

3.3. Production of Biomass [2]

3.3.1. Baker's Yeast

The production of baker's yeast exclusively for the production of bread doughs dates from the late 1800s. It started with the production on grain mashes, which were later replaced with the least expensive source of fermentable sugar, molasses.

During the last century the major advances in the production of baker's yeast have been the following:

1) Aeration: The stimulating effect of aeration on yeast growth was well known in the late 1800s, and continuous aeration of mashes was used in Britain in 1886.
2) Fed-batch process: The use of incremental feeding was introduced by Danish and German scientists between 1910 and 1920. This process is used today because it is the only practical method that permits production of yeast biomass without simultaneous production of large quantities of ethanol.
3) Molasses: Before 1920 the mash consisted of corn, malt, and malt sprouts. During the 1920s and 1930s, the grains were slowly replaced with molasses as carbon and energy source for yeast growth.
4) Active dry yeast: Progress was made in the late 1930s in the drying of compressed yeast (CY) to the more stable active dry yeast (ADY). Continued progress in the drying methods has led to ADY replacing CY in several bakery applications, particularly in institutional baking and in pizzerias.
5) Automation: During the past decades there has been a rapid shift to automatic control of the fermentation process.

Cane or beet molasses supply sugar as a carbon and energy source as well as organic nitrogen, minerals, sulfur, vitamins, and trace elements. The liquid growth medium must be supplemented with additional nitrogen (ammonia or ammonium salts) and phosphate, minerals (calcium and magnesium), vitamins, and trace elements.

Yeast is grown in large fermenters by the fed-batch process. The fermenters are equipped with cooling coils, and with means of vigorous aeration to maintain highly aerobic growth. In the fermenter liquid, 4 – 6 % of yeast solids can be produced.

Postfermentation processing begins with centrifuging to produce a concentrate (yeast cream) with 18 – 20 % solids. The yeast cream is washed and pressed or filtered to a semi-solid yeast mass of 30 % solids. The filter cake is packaged as a crumbly mass in bags or extruded in blocks that are wax wrapped. It is cooled and shipped refrigerated to bakeries. Some bakeries accept shipments of refrigerated yeast cream.

ADY is produced from the yeast cake by extrusion in the form of thin strands. These are dried on a continuous belt or in air-lift dryers. ADY with a solid content of 92 – 96 % is shipped in vacuum-packed or nitrogen-flushed pouches. It does not require refrigerated shipment or storage.

Until the early 1970s, two strains of *Saccharomyces cerevisiae* were used in the United States. The strain used for the production of baker's compressed yeast was grown to a nitrogen level of 8.2 – 8.8 % (dry weight basis). The ADY strain No. 7752 in the American Type Culture Collection was grown to a nitrogen level rarely exceeding 7 %. The lower nitrogen level favored the stability of the yeast, but resulted in a somewhat lower fermentation activity in comparison with compressed yeast on an equivalent solid basis.

A need for additional strains has arisen due to the following requirements of the baking industry: a dry yeast strain with improved fermentation activity, a yeast strain with exceptional fermentation activity in high-sugar dough, and yeast with improved performance in yeast-leavened frozen dough. Some new strains have now become available, but acceptance by the baking industry has been slow, partly because bakers do not like to deal with several strains in their bakeries, and partly because the production and distribution of several strains by yeast companies are more costly. Nevertheless, a trend towards more yeast strains for specialty applications can be expected.

Strains of baker's yeast for industrial production are preserved as pure cultures, usually on agar slants in test tubes. They are frequently transferred by well-known pure-culture methods. Commercial fermentations are started from such slants. Industrial strains of baker's yeast are quite stable.

Baker's yeast strains are available from public and private culture collections, and they can also be isolated from commercial baker's yeast since this yeast enters the market as a viable product. There are several patents protecting specific strains. Enforcement of such patent rights depends, of course, on the ability to identify the patented strain with certainty, which is often difficult.

Raw Materials.

Carbon and Energy Sources. Historically the major source of carbon for yeast growth was maltose derived from malt-converted grain mashes. Today, glucose, fructose, sucrose and a portion of raffinose from molasses serve universally as the carbon source. The discussion here is restricted to the growth of *Saccharomyces cerevisiae* on molasses and a brief indication of potential sugar sources from starches and whey.

Cane molasses is generally used in subtropical areas where cane is grown or in places to which it can be readily shipped by sea. In northern climates where sugar beet is extensively grown, and in areas distant from marine transportation, beet molasses is the major constituent of the mash. The price of molasses is largely determined by its value as a feed. In fermentation industry one of its major uses is the production of baker's yeast. At present, molasses is the cheapest source of fermentable sugars.

In the United States, mash bills contain at least 20 % cane molasses to supply enough biotin for yeast growth. Beet molasses is relatively easy to clarify, whereas cane molasses contains colloidal substances that make clarification more difficult. Molasses is deficient in nitrogen, phosphorus, and magnesium. These and some trace minerals and vitamins have to be supplied by enrichment of molasses or by separate addition to the fed-batch fermentation.

Beet and cane molasses are shipped at 80 – 85 Brix. They have a sugar content that varies between 50 and 55 wt %. Molasses can be stored well in large tanks often holding several thousand tonnes. It can be pumped at temperatures above 20 °C. Molasses contains some insoluble materials and some precipitation takes place on heating. Therefore, molasses is clarified. Cane molasses cannot be filtered well. It is clarified by addition of phosphates and sterilization followed by centrifugation. Beet molasses can be clarified in the same manner or by filtration. Prior to clarification, molasses is diluted with water to 30 – 40 Brix, which facilitates the process.

Some molasses is not satisfactory for the production of yeast. This may be due to the lack of or to insufficient concentrations of certain nutrients or to the presence of yeast-growth inhibitors, which may include fatty acids, nitrites, various insecticides or herbicides used in the field, or bactericides used in the sugar factory.

Beet molasses contains 1 – 1.5 wt % raffinose on dry solid basis. Baker's yeast strains assimilate only the fructose moiety of the raffinose molecule, which accounts for one-third of the trisaccharide content.

Nitrogen. Beet or cane molasses contains low concentrations of nitrogenous materials. Betaine nitrogen in beet molasses is not assimilated. A minor fraction of the low amino acid content of molasses is assimilated. In the production of baker's yeast, nitrogen is supplied in a readily assimilable form as ammonia, ammonium phosphate, ammonium sulfate, or urea.

Feeding of nitrogen in the form of ammonium sulfate or phosphate leads to liberation of sulfuric acid or phosphoric acid, which must be neutralized to maintain the desired pH range. When urea is used as a nitrogen source, fermentation requires higher levels of biotin.

Baker's yeast contains 6 – 9 % nitrogen. High nitrogen levels in the yeast result in higher activity but lower stability, both for compressed and active dry yeasts.

Minerals. Due to the low level of phosphorus in molasses, additional P should be added to the growth medium. The required concentration of phosphorus expressed as P_2O_5 should be one-third of the nitrogen concentration; thus 2 – 3 % P is supplied in the form of phosphoric acid or its salts such as ammonium phosphate. Molasses contains sufficient potassium, calcium, and sulfur, but is low in magnesium, which must be added to the growth medium.

Vitamins. Baker's yeast strains require biotin for growth. Cane molasses supplies ample

amounts of this vitamin, usually 0.5 – 0.8 ppm. Beet molasses contains only traces of biotin. Therefore, at least 20 % cane molasses is used in beet/cane blends for yeast production. For fermentation of carbohydrate sources that contain little or no biotin (e.g., corn syrup and date concentrate) the synthetic vitamin can be added at a rate of 60 – 100 µg per 100 g of yeast solids grown.

Molasses contains sufficient amounts of other vitamins including pantothenate, thiamin, pyridoxine, and nicotinic acid. Baker's yeast can synthesize thiamin from thiazole and pyrimidine compounds, and there is no absolute need for thiamin. However, concentrations above 100 µg/g of yeast solids in American commercial baker's yeast indicate that thiamin has been added to the growth medium. Such high levels of thiamin do not improve growth rate or yield, but have a small but demonstrable effect on yeast fermentation activity.

Alternative Carbon Substrates. Molasses is the least expensive source of sugar for growing baker's yeast, but its price occasionally fluctuates and may approach that of corn-derived sugars. Therefore, other carbohydrate sources have been investigated, including hydrolyzed lactose from cheese whey, and hydrolyzed starch. For growth of baker's yeast the hydrolysis of starch by commercial amylases would be more cost effective.

Fermentation Activators and Inhibitors. Activators are the nutrients required for the successful completion of the fermentation process. Activators include P, Mg, K, Na, Mn, and S. Only the trace elements (Cu, Fe, and Zn) are essential for yeast metabolism. They become integral part of the proteins as activators of enzymes and function as cofactors in biochemical reactions within the cell.

Fermentation inhibitors include heavy metals at very low concentrations. SO_2 also inhibits yeast growth, but there is good adaptation even at concentrations of 80 – 100 ppm. Molasses contains variable amounts of nitrate that can be reduced to nitrite by bacterial action during growth. Yield losses due to nitrite inhibition have been reported for nitrite concentrations of 0.001 – 0.004 %.

Contamination. Baker's yeast always contains some contaminating organisms since it is grown in fermenters that cannot be kept completely sterile.

Specifications for baker's yeast require absence of Salmonella and other pathogens, and restrict the number of coliform organisms to less than 1000 per gram and the count of *Escherichia coli* to less than 100 per gram. Baker's yeast plants follow Good Manufacturing Practice (GMP) rules of the Food and Drug Administration, and great efforts are made to keep the number of contaminants to a minimum.

Molasses is generally sterilized in bulk or in continuous heat exchangers. The air used to aerate the fermenter is passed through depth filters or membrane filters, or is heated. Fermentation tanks are thoroughly cleaned by hot alkaline solutions or detergents, usually with clean-in-place (CIP) equipment, and if necessary by scrubbing.

All pipes, pumps, valves, and other auxiliary equipment must be thoroughly sanitized. It is also important to consider potential contamination from other accessory equipment such as air pipes, leaking cooling coils, probes for pH meters and other instruments and sampling devices. Particular attention has to be paid to ducts for exit air to prevent condensate from dripping back into the fermenter. Similar attention must be paid to further processing of the grown yeast, which includes the centrifuges, presses, filters, and all packaging operations. For active dry yeast it includes the dryers. Yeast is an excellent growth medium for bacterial contaminants, and deposits of wet or dry yeasts on equipment become a ready source of infection.

The overwhelming proportion of contaminants in CY or ADY are lactic acid-producing organisms which almost always belong to the heterofermentive lactic acid-producing organisms of the genus Leuconostoc or to the homofermentive bacteria of the genus Lactobacillus. Some coliform organisms and occasionally a few *Escherichia coli* can be found. Active dry yeast made by drying compressed yeast contains the same kinds of microorganisms, but the total count generally decreases during drying and upon subsequent storage of the dried yeast. Specifications for rope spores require an upper limit of 200 per gram ADY.

Occasionally contamination with Oidium or other molds has been reported. Various species of contaminating yeast have also been reported,

most of them falling into the genera Candida and Torulopsis.

3.3.2. Active Dry Yeast

Baker's yeast can be dried in its vegetative state to a product having less than 8 % moisture without substantial loss of viability, but success of the drying method requires mastery of the various requirements of the methodology.

In addition to the household market, ADY is now also used extensively by retail bakers, institutional users, pizza chains, and in all areas in which it is impossible or too expensive to distribute refrigerated CY. The latter has not been replaced in major wholesale bakeries.

Until a few years ago almost all the ADY was produced with strain No. 7752 of the American Type Culture Collection, which gives a better yield on a sugar basis. Its cells are larger than those of strains used for the production of compressed yeast. There is some loss of solids during the early stages of drying due to increased respiration. This strain can be dried in continuous tunnel (chamber) dryers with minimal loss of fermentation activity.

Efforts to improve the properties of dried yeasts have been concerned with questions of yeast composition, strains, and improved methods of drying. With regard to composition, it was found that the trehalose concentration should be 12 % or higher (solid basis). It was also found that compressed yeast used for the production of ADY must be thoroughly washed to reduce the concentration of water-soluble substances in the extracellular aqueous solutions. Retention of residual salt, resulting from acid treatment is particularly harmful during drying.

For a given strain, the fermentation activity is considerably higher in yeast grown to a higher nitrogen level, but such yeasts are also more sensitive to drying. Hence, the search for better methods of drying assumed particular importance. Methods are sought that would permit drying at a lower temperature, in a shorter period of time, and with much smaller particles of press cake to improve the uniformity of moisture removal. Some success has been achieved with a fluid-bed drying method, a drying time of less than two hours, and a yeast strain with a nitrogen content of more than 8 %. The resulting ADY has a smaller particle size and more regular shape than ADY dried in tunnel dryers. This type of dry yeast is called instant active dry yeast (IADY) because it does not require separate rehydration before use.

Numerous patents have claimed certain strains of *Saccharomyces cerevisiae* as particularly useful in production of ADY, often in conjunction with definite processing conditions. Such strains are produced by classical hybridization, protoplast fusion, or mutation.

Many compounds added to the yeast cream or to the press cake are claimed to produce a more active ADY or IADY. Methyl cellulose or carboxymethyl cellulose have been suggested as suitable "swelling" agents at 1 – 2 % of the yeast solids. Emulsifiers such as monoglycerides, soya lecithin, glycerol polyesters, and sorbitan esters will also help maintain the yeast activity. In practice, sorbitan esters are widely used at levels of 0.2 – 1 %. The added emulsifier facilitates processing and lightens the color of ADY or IADY, but the main reason for use of these compounds is the reduction of leached solids when ADY is rehydrated.

Active dry yeast loses activity upon storage when exposed to atmospheric oxygen. Storage stability can be increased by addition of an antioxidant such as butylated hydroxyanisole (BHA) at about 0.1 % based on yeast solids to yeast cream before pressing or filtration. The antioxidant is dispersed with the aid of an emulsifier, preferably a sorbitan ester. The treatment is effective for ADYs with a moisture content of < 6 %. The storage stability of such "protected" ADY is considerably enhanced. However, it does not match the extended stability that can be achieved by complete exclusion of air during storage.

For use in baking ADY must be rehydrated in water at 30 – 40°C. Rehydration at lower water temperature lessens the fermentation activity of ADY. The material leached from the yeast cells, as a result of rehydration, has a slackening effect on doughs due to the extraction of reducing compounds such as glutathione or cysteine. In many dough systems slackening is not desired. However, for bucky dough made from very strong flours, slackening may be desired, but it is better achieved in a controlled fashion by the addition of proteolytic enzymes or cysteine to the dough.

IADY need not be rehydrated in water, but may be mixed in with other dry dough ingredients. Its activity is better upon direct incorporation than with separate rehydration, possibly due to the difference in moisture content between ADY and IADY.

The storage stability of ADY is decreased by higher temperature, higher moisture content of the yeast, and by the presence of air in the package. ADY loses about 7 % of its fermentation activity per month if improperly stored without a protective inert atmosphere at ambient temperature. For storage under nitrogen, or when vacuum packed, the loss is about 1 % per month and generally less than 10 % per year.

Accelerated storage tests under the effect of various atmospheres and temperature approaching 55°C have been tried. Such accelerated tests are useful for purposes of quality control. They do not provide reliable information on commercial conditions unless they have been correlated with long-term storage at normal temperatures.

IADY is always distributed in hermetically sealed pouches in vacuo or flushed with an inert gas. ADY absorbs CO_2 readily. When used with large packages, a sufficient vacuum is created to give the appearance and performance of a vacuum packaging.

The packages may be nitrogen-flushed tin or aluminum foil pouches with low permeability to water vapor and gaseous oxygen. The aluminum foil, which must be free from pin holes, is laminated to a heat-sealable plastic film such as saran or pliofilm.

Once the package has been opened the ADY should be used quickly. In particular, it should not be exposed to an atmosphere with high humidity.

Inactive dried nutritional yeast is produced from a yeast cream of about 18 % solids by pasteurization followed by drum drying or spray drying. The spray-dried product has very fine particles. The drum-dried product that exits the drums as a thin sheet is available as small flakes or ground to a powder.

Spent excess brewer's yeast is recovered in breweries by sedimentation or centrifugation. It contains 12 – 16 % total solids, of which approximately two-thirds are yeast solids and one-third are beer solids. The slurry must be kept refrigerated before use because even at 4°C respiration lowers the carbohydrate content. This yeast may be pasteurized and dried as such to a rather bitter dried brewer's yeast, or the yeast may be separated from the beer by decanter or nozzle centrifuges and partially debittered. It is also pasteurized and dried. Distiller's yeast is not recovered as a separate product because of the presence of other insolubles in the still residues.

3.3.3. *Candida utilis* (Torula) Yeast

Torula is a common commercial trade name for dried nutritional and feed yeasts. The major substrate for its production in the United States are sulfite waste liquors of the paper pulp process, and in Europe and former Eastern Bloc countries they are wood hydrolysates or sulfite waste. *Candida utilis* is grown on wood sugars because it assimilates both pentoses and hexoses, and its growth requires the addition of nitrogen sources, phosphate, and potassium to the medium. In contrast to *S. cerevisiae*, the Candida yeast does not require the addition of biotin.

*C. utilis*is produced by continuous homogeneous fermentation, which can be run for months. The yield of yeast is generally 50 % based on fermentable pentoses plus hexoses. The yeast is recovered by centrifugation. After minimal washing with water *C. utilis* can be sold as feed yeast, which contains a considerable amount of lignosulfonic acids. For use as human food, the yeast must be centrifuged at least twice with extensive washing. Dried yeast is obtained by drum or spray drying.

3.3.4. Dairy Yeasts

Large amounts of cheese whey are available as a byproduct of cheese production. The whey may be dried and sold as food or as feed ingredients, but supply by far surpasses demand. Thus, there exists a problem of waste disposal and there have been numerous attempts to use whey as a fermentation substrate for the production of ethanol and biomass.

Dairy yeasts are lactose-assimilating and lactose-fermenting yeasts; the preferred species for the production of biomass is *Kluyveromyces marxianus.*

3.3.5. Brewer's Yeast

Yeast plays an important role in the brewing process not only by converting fermentable sugars in the wort to ethanol and carbon dioxide but also by producing a variety of volatile and nonvolatile constituents, mostly in trace amounts, that contribute to the whole flavor of the beer.

Two species of the genus Saccharomyces are often considered important for brewing depending on the type of the brewing process.

Most beers are produced by the bottom fermentation process in which strains of the yeast *S. uvarum* are used. These yeasts have a tendency to remain suspended for a limited time in the fermentation medium while the fermentation is active, after which they settle to the bottom of the fermentation vessel. This strain is predominantly used in Germany and North America for the production of lager beer.

The other type of beer, referred to as ale, is produced by a top fermenting yeast such as *Saccharomyces cerevisiae*. The strains tend to rise to the top of the fermenting medium and are generally skimmed off the surface of the fermenting liquid after the fermentation is completed. Ales are popular in England and Ireland.

Malt extract or beer wort is one of the oldest classical media for growing yeast cultures. It contains nitrogen, mineral salts, and vitamins in amounts adequate for maintaining yeast growth, and fermentable carbohydrates to supply carbon and energy for biosynthesis. There is also an absolute requirement for molecular oxygen. The yeast can, however, exhibit some growth under completely anaerobic conditions.

3.3.6. Wine Yeasts

Fermentations of fruits and fruit juices occur naturally and spontaneously without human intervention. Ripe berries can undergo spontaneous fermentation in the field if they are overripe or damaged.

These fermentations are initiated by yeasts found on the grape skin. Yeasts survive from year to year in the intestines of bees and wasps and they are readily transferred during the crushing season by fruit flies (*Drosophila melanogaster*) during the transport of grapes to the winery and within the winery. Once the crushing season is underway, the major source of yeasts is likely to be found on winery equipment such as crushers, destemmers, and tanks.

The terms brewer's yeast and baker's yeast are restricted to certain specific strains of *Saccharomyces cerevisiae*. These yeasts are almost always produced from selected pure strains of this species. In contrast, wine yeasts are strains of various species participating in must fermentation.

In a broad sense, any yeast species occurring on grapes and participating in must fermentation, no matter how transient, may be called a natural yeast. In a narrow sense, strains grown on pure culture in winery fermentations are wine yeasts. Such strains generally belong to the species *Saccharomyces cerevisiae*.

A large number of yeast cells found on grapes belong to the genera Kloeckera, Hanseniaspora, and to a lesser extent to the genera Metschnikowia and Candida.

There is a considerable increase in cell counts as the grapes are transported and the must is prepared in the winery. The fermentation is initiated by weakly fermenting yeast, mainly *Kloeckera apiculata*. The early fermenters are replaced by more alcohol-tolerant yeasts, and during the main part of the fermentation and toward the end the true wine yeasts *S. cerevisiae* dominate.

3.3.7. Distiller's Yeasts

Distiller's yeasts include strains of *S. cerevisiae*, except for natural fermentation, in which any number of species may be involved. Yeasts suitable for grain fermentations can be baker's compressed yeast, distiller's active dry yeast, or strains grown in the distillery from selected pure-culture slants.

The fermentation of the various raw materials is best understood by categorizing them into the fermentation of cereal mashes, which contain all the constituents of cereal (whisky and sake), and the fermentation of juices and liquid extracts, which contain all carbohydrates in the form of fermentable sugars (fruit juices, molasses, and fully hydrolyzed starches). Cereal mashes are characterized by the concurrent enzymatic formation of sugars, and their fermentation, at least in the latter stages of the process.

4. Yeast-Derived Products

4.1. Flavor Products

Yeast extracts are commercially available as a powder or paste and have been used extensively by the food industry as flavoring agents. They are concentrates of the soluble fraction of yeast, generally made following autolysis, which is essentially a degradation process carried out by activating the yeast's own degradation enzymes to solubilize the within-cell components.

Yeast extracts can also be made by hydrolysis with external reagents or enzymes capable of releasing the cell contents. Yeast extracts have received wide acceptance in the food industry as natural flavors. They are also cost-effective compared to other synthetic food flavors, on the basis of equivalent flavor intensity.

They are used extensively in the fermentation industry and as a complex nutritional source for the preparation of microbiological growth media for plate assays. The production of yeast extracts worldwide is ca. 32 000 t.

Surplus yeast from the brewing industry is relatively cheap and is utilized in the production of extracts to meet the needs of the food and fermentation industries.

Extracts made from primary-grown yeast such as *Saccharomyces cerevisiae* (baker's), *Candida utilis*, or *Kluyveromyces marianus* have flavor profiles somewhat different from those of brewer's yeast. The latter is likely to have undesirable flavor characteristics as a result of a carryover of hop resins and beer solids.

Autolysate is the total content of yeast following autolysis. The product is in the form of a concentrated paste or dried without separation of the particulate matter. Consequently, autolysates are less intense in flavor than extracts on an equal weight basis because of the dilution effect of the cell-wall material.

4.2. Nutritional Yeast

Yeast is generally recognized as an excellent source of proteins, B vitamins, fiber, and many other micronutrients. However, excessive intake of yeast has caused serious human health problems which were later identified as being due to excessive consumption of nucleic acid present in yeast. Decrease of nucleic acid content is often carried out following the separation of yeast proteins in crude form from the whole cell. Yeast is ruptured using several methods including high-pressure homogenization, colloid mill, sonic desintegration, freeze – thaw treatment, use of lytic enzymes, or a combination of these methods for maximum recovery. Several methods to lower the level of nucleic acid have been described in the literature.

4.3. Colorants Derived from Yeast

In the last decade or so, there has been considerable interest in developing food colorants from natural products. Although different types of natural pigments are widely distributed in the plant and animal kingdoms, a variety of carotenoid pigments of various pink and yellow shades are also produced by a number of yeast species. Yeast offers considerable advantages over other natural sources in that it is inexpensive to grow on an industrial scale. Yeast has now begun to emerge as a cost-effective source for the production of natural food colorants.

The best-known genera among the pigmented yeasts are Rhodotorula, Rhodospondium, Cryptococcus, Sporidiobolus, and Sporobolomyces. These yeasts are characterized by their ability to produce pigments such as β-carotene, α-carotene, torulene, torularhodin, plectanisxanthin, and 2-hydroxyplectanisxanthin.

Carotenoids produced by different Rhodotorula species contain primarily the two oxygenated compounds torulene and torularhodin, and the ratio of the two major pigments determines the intensity of the shades of red in different species.

Phaffia rhodozyma is a basidiomycetous yeast that differs from other pigmented yeasts in producing astaxanthin, which is widely distributed in the animal kingdom. Much of the interest in astaxanthin is due to the fact that it is responsible for the characteristic color in the plumage of birds such as flamingos, in the exoskeleton of marine invertebrates such as lobsters, crabs, and shrimps, and in fish such as trout and salmon, whose pink color is due to the storage of the pigment in their flesh. Lack of the characteristic pink color in pen-reared salmonids renders them less acceptable. Astax-

anthin can restore the pink color in seafood, resulting in better marketability.

4.4. Yeast-Derived Enzymes

Invertase is an enzyme capable of splitting the sucrose molecule into glucose and fructose, a noncrystallizable mixture known as invert sugar. It is sweeter than sucrose on an equivalent weight basis due to the higher sweetening power of fructose. As a result, invert sugar is generally regarded as an important ingredient in the food and confectionery industries.

Baker's yeast is rich in invertase and is the main source of commercially available invertase.

There are two important applications of invertase in the food industry. The first is in the manufacturing of confectionaries, where invertase is used mainly in the production of soft-centered candies. The use of invertase provides the plastic consistency to the center and prevents sucrose from crystallizing during storage. The enzymatic hydrolysis that brings about the creamy consistency of the center generally takes place after casting and covering the hard center with chocolate. The second important application is in the inversion of syrups for the production of high-test molasses, used extensively in the fermentation industry. High-test molasses, if not inverted, would soon tend to crystallize due to high concentration of sucrose. Inversion also raises the osmotic pressure and results in a microbiologically stable concentrate with a consistency that is easy to handle.

The most common method of extracting and concentrating invertase from yeast is by autolysis and to recover the enzyme from the filtered autolysate by precipitation or concentration. The precipitating agents commonly used are ethanol, acetone, and ammonium sulfate. The precipitate thus formed is dissolved in water, filtered, and treated with activated carbon to remove coloring matter, followed by concentration under vacuum, or by ultrafiltration.

Invertase is commercially available as a concentrate stabilized with glycerol.

Lactase catalyzes the hydrolysis of lactose (milk sugar) into its principal components, glucose and galactose. This enzyme is widely used in the food industry for the treatment of frozen whole-milk concentrates to prevent crystallization during storage, and most importantly to make milk-based products acceptable for those who cannot tolerate lactose.

Lactase is not present in baker's yeast, but it is present in a number of other common yeasts.

Melibiase hydrolyzes the disaccharide melibiose to glucose and galactose. Consequently, there is likely to be a potential market for this enzyme, specifically to improve the production yield in the beet sugar industry.

In the production of beet sugar, raffinose, a trisaccharide (galactose – glucose – fructose), is known to hamper the crystallization process and thereby reduce extract yields. This results in a high concentration of raffinose and sucrose in the final molasses. Melibiase splits raffinose into galactose and sucrose. This treatment not only increases the recovery of sucrose in the syrup but also minimizes the raffinose content, therefore enhancing the beet sugar crystallization process.

A potential application for melibiose is in the baker's yeast industry. Although the predominant sugar in both beet and cane molasses is sucrose, beet molasses contains 1 – 1.5 % raffinose (solid basis). Only one-third of this trisaccharide is utilized by baker's yeast due to the presence of invertase, which converts raffinose into melibiose and fructose. The latter is assimilated by the yeast. For complete utilization of raffinose molecule the enzyme melibiase should either be added to the wort, wort should pass through a column of beads containing immobilized melibiase, or the baker's yeast strain must be genetically altered to produce melibiase.

Other enzymes produced commercially by yeasts include alcohol dehydrogenase, hexokinase, L-lactate dehydrogenase, glucose-6-phosphate dehydrogenase, phenylalanine ammonia lyase, and glyceraldehyde-3-phosphate dehydrogenase.

4.5. Pharmaceutical and Cosmetic Products

Skin Respiratory Factor. A yeast-derived product with wound-healing properties is commercially available for the production of hemorrhoidal preparations and is often referred to as skin respiratory factor (SRF) of live yeast cell derivative (LYCD). SRF prepared from yeast is known to exhibit certain biological properties

capable of enhancing the oxygen uptake rate, thereby stimulating wound healing. Its effectiveness in skin care has made it a commercially attractive ingredient for the cosmetic and pharmaceutical industries.

Glycan. The term glycan is used broadly to refer to commercial preparations of the insoluble yeast cell wall fraction. It is generally recovered as a byproduct during the production of soluble extracts from baker's or brewer's yeast. Yeast cell wall is made up of glucan, mannan, and chitin polymers that are nutritionally nonfunctional in the human digestive tract. The three components account for more than 80 % of the dry matter of the glycan fraction, and about 20 % is noncarbohydrate material, including protein, nucleic acid, lipids, and ash.

A desirable property of glycan is its ability to function as a noncaloric food thickener. It provides a fat-like mouthfeel, thus permitting its use as a fat replacer in the production of low-calorie salad dressings, cheese analogs, and frozen desserts such as ice cream.

Its high water-holding capacity has made it a useful ingredient in the formulation of sausages, hot dogs and certain other meat-based products.

More recent research has begun to show certain unique properties in glycan that are likely to permit its use as a remedy for certain human disorders.

Recent studies have demonstrated the beneficial effect of glycan in improving host resistance by enhancing both humoral and cellular immunity to certain malignant tumors and viral infections. The therapeutic effect of glycan is primarily due to stimulation of the reticuloendothelial system (RES), which in turn produces increased amounts of macrophages that play a key role in the body's natural immune system. The macrophages absorb and destroy invading particles by phagocytosis.

Coenzyme A Synthesizing Protein Complex. Research is presently underway to develop methods for the detection of cancer at an early stage, long before any symptoms become apparent in the patient. One such diagnostic techniques involves the early detection of β-protein in the bloodstream, which is an early indication of the body's reaction to cancer.

A biologically active compound referred to as coenzyme A synthesizing protein complex (COA-SPC), derived from baker's yeast, has found application as one of the components used for detecting β-protein in human blood.

The biologically active COA-SPC complex has been identified in the particulate fraction following the lysis of baker's yeast.

Genetically Engineered Products from Yeast. With the technological advances that have already been made in genetic engineering, substantial effort has now gone into the development of methodology to manipulate and modify the yeast genome. Yeast has become one of the most frequently exploited microorganisms, capable of producing valuable products of commercial importance (see also → Genetic Engineering, Chap. 4.2.1., → Genetic Engineering, Chap. 4.2.2.).

Despite the exceedingly long lag time and high expense of putting new products through the entire approval process, at least a few biotechnology companies have been able to bring certain genetically engineered yeast-derived products into the final stages of marketing. More genetically engineered products are in human clinical trials and are being evaluated for final approval.

At present, the list of commercial products includes only three well-known products: human insulin, interferon, and hepatitis-B vaccine.

1. Introduction

The exact definition of the term "zeolite" is still the subject of discussion [1–4]. A version in general use is due to BARRER [1] and BRECK [5], which states that zeolites [*1318-02-1*] are crystalline, hydrated aluminosilicates with a framework structure. Their three-dimensional, polyanionic networks are constructed of SiO_4 and AlO_4 tetrahedra linked through oxygen atoms. Depending on the structure type, they contain regular channels or interlinked voids whose aperture diameters are in the micropore range. These pores contain water molecules and the cations necessary to balance the negative charge of the framework. The cations, which are mobile and can be exchanged, are mainly alkali metal or alkaline earth metal ions.

Formula **1** accords with these characteristics. The expression enclosed in the square brackets shows the composition of the anionic framework in the crystallographic unit cell. M represents the nonframework metal cation, and n is its charge. Formula **2** occurs frequently in the literature and, unlike Formula **1**, simply represents the overall chemical composition.

$$M_{x/n}[(AlO_2)_x(SiO_2)_y] \cdot z\,H_2O \quad \mathbf{1}$$

$$M_{2/n}O \cdot Al_2O_3 \cdot y'\,SiO_2 \cdot z'\,H_2O \quad \mathbf{2}$$

Many synthetic zeolites also occur naturally as minerals. The observation that a certain mineral began to bubble on strong heating led CRONSTEDT in 1756 to give the name "zeolites" to such materials from the Greek *zeo*: to boil and *lithos*: stone [6], [7]. However, zeolites only became of industrial importance in the 1950s, when synthetic examples became available on an industrial scale [8]. Since then, world consumption of synthetic zeolites in the fields of ion exchange, adsorption, and catalysis has grown continuously. The total for 1993 exceeded 10^6 t, mainly a consequence of the use of the zeolite NaA as a detergent builder. Zeolites are also important as adsorbents for separating and purifying substances and as catalysts in a number of important processes in the chemical and petrochemical industries.

In addition, ca. 300 000 t/a natural zeolites are sold worldwide. Their main uses are as ion ex-

changers for water treatment, in soil improvement, in animal feeds, in cat litter, and in pozzolanic cement.

The wide range of commerical applications has stimulated intensive investigation of the chemistry and physics of the zeolites [5], [9–19]. Current research is increasingly concerned with zeolite-like molecular sieves, which have expanded the field of zeolites enormously during the last two decades. In these new materials, the aluminum and silicon of the classical zeolites are partially or completely replaced by other elements [20], [21]. The most important groups of these molecular sieves are:

1) Modifications of silica ("zeosils," see → Silica, Chap. 8.2.1.)
2) Metallosilicates with tri- and tetravalent heteroatoms in place of aluminum as framework components, e.g., boro- and gallosilicates [22], ferrisilicates [23], and titanosilicates [24]
3) Alumino- and gallophosphates and compounds derived from them [25–27]

These compounds generally have framework structures analogous to those of the zeolites. Some new structures have been discovered, too. However, with a few exceptions, these compounds are still of rather limited economic importance, and are discussed here only briefly.

2. Nomenclature

The naming of zeolites in the literature seldom follows a scientific system. If natural analogs exist, the synthetic zeolites are often named after the minerals (e.g., faujasite, mordenite, ferrierite, and offretite). Alternatively, the names given by the discoverers are used. In the 1950s and early 1960s, new synthetic zeolites were named using the letters of the Latin and Greek alphabets. Examples include the Linde molecular sieves A, L, X, and Y of Union Carbide and the zeolites beta, rho, theta-1, and omega. Acronyms that indicate the industrial or university laboratory that first synthesized a given material were then increasingly used, supplemented by a consecutive numbering system. Names such as ZSM-5 (Mobil Oil), Nu-13 (ICI), LZ-210 (Union Carbide/UOP), CSZ-3 (Grace), and ECR-1 (Exxon) have gradually become generally accepted.

Zeolites with identical framework structures can therefore appear in the literature under different names. Some order has been imposed by the introduction of a classification system in the *Atlas of Zeolite Structure Types* [28], which indicates which different materials have the same structure type. The structure types themselves are denoted by the combination of three capital letters. For example, the type LTA is found in zeolite A, FAU in the faujasites X and Y, and MFI in the ZSM-5 family of zeolites.

CAS numbers are available for only a few zeolites. Moreover, as these are rarely used, they are of little benefit in literature searches.

3. Structure, Composition, and Properties of Zeolites

3.1. Framework Structure and Positions of Nonframework Cations

The third edition of the *Atlas of Zeolite Structure Types* [28], published in 1992, describes 85 different structures, including both classical zeolites and zeolite-like molecular sieves. The majority of these structures can be represented by Formulas **1** and **2**, but a few have been found to occur only as alumino- or gallophosphates.

Zeolites are classified structurally as tectosilicates [3]. The basic elements of their frameworks are TO_4 tetrahedra (T = Si, Al) linked through oxygen atoms. The description and classification of the topology of zeolites is based on the concept of larger units known as secondary building units (SBUs) [28]. These can consist, for example, of simple rings and prisms of various sizes. By combining such basic units the known zeolite frameworks can be constructed. Alternative concepts are based on more complex chains or layer structures known as structural subunits (SSUs) [29].

The most readily visualized structural units are polyhedra such as the truncated octahedra known as sodalite cages or β-cages, found in the structure of the industrially important zeolites A, X, and Y. Figure 1 shows the sodalite unit and the framework structures of the zeolites. In this representation, the tetrahedrally coordinated silicon and aluminum atoms are symbolized by

Figure 1. A) Sodalite cage or β-cage; B) Framework structure of zeolite A (structure type LTA) with α-cage; C) Framework structure of faujasite (structure type FAU; zeolites X, Y) with supercage

vertices, and the oxygen atoms are located between these.

The principal characteristic of all the structures is the well-defined system of regular cavities or channels which is essential for application of zeolites as molecular sieves. In zeolite A (type LTA), the β-cages are linked together via cubic units to form a larger cavity with the shape of a truncated cubo-octahedron. These so-called α-cages (diameter 1.14 nm) are interconnected by windows formed by rings consisting of 8 T atoms, giving a three-dimensional pore system. If the β-cages are linked together by hexagonal prisms, this results in the faujasite structure (type FAU). In this case also, the linking leads to a larger cage. This is known as a supercage because of its large diameter (ca. 1.20 nm), and has windows formed by 12 T atoms.

Whereas the cavities in the LTA and FAU structure types are characteristically in the form of interlinked cages, the MOR type (mordenite) and the MFI type (e.g., ZSM-5) contain channel systems, as shown in Figure 2. The MFI structure is easier to visualize if only the cavity structure is represented, and not the framework structure. Linear parallel ten-ring channels are linked together by zig-zag shaped continuous pores with ten-ring apertures perpendicular to the channels, resulting in a three-dimensional cavity system. In contrast, the pore system of mordenite is two-dimensional, the 12-ring channels being in effect only one-dimensional.

The various zeolite structures differ not only in the type and dimensionality of their pore systems, but also in the size of the pore apertures. Narrow-pore, medium-pore, and wide-pore zeolites have different pore apertures formed by rings of 8, 10, or 12 T atoms, with corresponding crystallographic diameters of 0.35 – 0.45, 0.45 – 0.60, and 0.60 – 0.80 nm [5], [30]. In the zeolites themselves, pore apertures larger than these have not so far been observed, although they do occur in the alumino- and gallophosphates, in which structures containing 14-, 18-, and 20-ring apertures are known, with diameters ranging from 0.80 to 1.45 nm [31], [32]. The pore apertures of the industrially important synthetic zeolites are listed in Table 1, together with other characteristic data for these materials [5], [30], [33]. It can also be seen from the table that the apertures can deviate to varying extents from circular. For example, the cross-section of the zig-zag pores in ZSM-5 is distinctly elliptical.

The regular nature of the pores and their apertures, whose dimensions are of the same order of magnitude as molecular diameters, enables the zeolites to function as molecular sieves. This is the outstanding property of zeolites that gives them their value as selective adsorbents for separating substances and as shape-selective catalysts (see Sections 7.2 and 7.3). Depending on the zeolite type and its pore system, molecules can penetrate into the cavity system or be excluded from it (Fig. 3).

The concepts of kinetic molecular diameter and effective pore size take account of the fact that the adsorptive molecules and the zeolite framework are not rigid, but undergo thermal vi-

brations. Therefore, the selectivity of the exclusion of molecules whose diameters are similar to that of the zeolite apertures determined crystallographically depends on temperature. Thus, the crystallographic diameter of the 6-ring aperture of the β-cage, as in type A, X, and Y zeolites, is given as 0.22 nm. However, at room temperature, water molecules with a kinetic diameter of 0.26 nm can readily penetrate into the β-cage, so that this should be regarded as the effective pore aperture.

Figure 2. A) Framework structure of mordenite (structure type MOR) represented as linked SiO_4/AlO_4 tetrahedra; B) Hollow tube representation of ZSM-5 (structure type MFI)

The apparent pore diameter can also be varied by using cations of different sizes. Figure 3 illustrates this for the example of zeolites KA, NaA, and CaA.

Nonframework Cations. The cations needed to balance the negative charge on the zeolite framework occupy definite positions in the cavities and channels, where they are surrounded by partially negatively charged oxygen atoms from the rings of the framework. The framework – cation bond thus has a mainly ionic character. The preference of particular cations for particular available sites can be due to energetic, steric, and coordinative considerations [34–36]. In the presence of adsorptive molecules, a redistribution of the cations is possible. The nature and distribution of the cations in the framework are of importance when zeolites are used as adsorbents and catalysts. Any change can lead to differences in both apparent pore diameter and charge distribution.

Positions and distributions of cations in A-type and faujasite-type zeolites have been researched most thoroughly [35], [36]. In the latter type, the most important positions are the centers of the hexagonal prisms, in which octahedral coordination is possible, and positions close to the centers of the hexagonal surfaces in the supercage and β-cages (see Figure 1 C). The pattern of occupation of available sites depends on the particular cations and on whether the zeolite is anhydrous or hydrated.

A special situation arises if the zeolite is converted into the so-called hydrogen form in which the framework charge is formally balanced by H^+. In this case, acidic OH groups are bonded to the framework (see Section 7.3).

3.2. Chemical and Physical Properties

Most of the chemical and physical properties of the zeolites, and hence their areas of use, are essentially determined by the aluminum content of their frameworks. In the literature, this is usually expressed by the Si/Al or SiO_2/Al_2O_3 ratio (y/x in Formula **1** and $y' \approx 2\,y/x$ in Formula **2**).

According to the Loewenstein Rule, Al – O – Al groups cannot occur in crystalline aluminosilicates [37]. Hence, an SiO_2/Al_2O_3 ratio of < 2 is impossible for zeolites. As can be

Table 1. Structures and compositions of some industrially important synthetic zeolites

Zeolite	Structure type [28]	Dimenisonality of pore system	Window	Pore apertures, nm	SiO_2/Al_2O_3	Typical composition of unit cell
A	LTA	3	8-ring	0.41	2.0 – 6.8	$Na_{12}[(AlO_2)_{12}(SiO_2)_{12}] \cdot 27\,H_2O$
P	GIS	3	8-ring	0.31 × 0.45 0.28 × 0.48	2.0 – 5.0	$Na_6[(AlO_2)_6(SiO_2)_{10}] \cdot 12\,H_2O$
ZSM-5	MFI	3	10-ring 10-ring	0.53 × 0.56 0.51 × 0.55	25 – ∞	$(Na,TPA)_3[(AlO_2)_3(SiO_2)_{93}] \cdot 16\,H_2O$ *
X	FAU	3	12-ring	0.74	2.0 – 3.0	$Na_{86}[(AlO_2)_{86}(SiO_2)_{106}] \cdot 264\,H_2O$
Y	FAU	3	12-ring	0.74	3.0 – 6.0	$Na_{56}[(AlO_2)_{56}(SiO_2)_{136}] \cdot 250\,H_2O$
Mordenite	MOR	2	12-ring 8-ring	0.65 × 0.70 0.26 × 0.57	9.0 – 35	$Na_8[(AlO_2)_8(SiO_2)_{40}] \cdot 24\,H_2O$

* TPA = Tetrapropylammonium.

Figure 3. Correlation between the effective pore size of industrially important zeolites and the kinetic molecular diameter of selected compounds (room temperature)

seen for the synthetic zeolites in Table 1, each structure type exhibits a phase breadth with respect to the SiO_2/Al_2O_3 ratio. A distinction can be made between low-silica ($SiO_2/Al_2O_3 < 4$), intermediate-silica ($4 < SiO_2/Al_2O_3 < 20$), and high-silica ($20 < SiO_2/Al_2O_3 < 200$) zeolites, and zeosils, in which aluminum is present only as a trace impurity (→ Silica, Chap. 8.2.1.) [38]. In some intermediate-silica zeolites, a higher SiO_2/Al_2O_3 ratio can be produced by post-synthetic dealumination (see Section 6.3.2).

The aluminum atoms may not be uniformly distributed over the cross section of the zeolite crystal. More often, and especially with synthetic high-silica zeolites, a zoning effect has been observed [39], [40], which is important in catalytic applications.

Physical Properties. Synthetic zeolites containing alkali metal and alkaline earth metal cations are normally colorless crystalline powders. Colors only occur if the zeolites contain transition metals as impurities or if they have been modified by ion exchange with these elements. As a rule, the primary particles of industrially synthesized zeolites have an average size of 0.1 – 15 µm, although crystals with diameters of up to 5 mm can be produced under special conditions [41]. The single crystals often form larger aggregates. Like slurries of many other finely divided substances with surface-active groups, suspensions of zeolites can exhibit thixotropy or rheopexy, which is relevant in production processes.

On heating, hydrated zeolites release water. Many zeolites can be almost completely freed of adsorbed water without major alteration of their crystal structure by calcination at 400 – 500 °C, leaving solids with large free pore volumes and interior surfaces whose extent depends on the framework density of the particular structure type [28] and on the number and nature of the cations. The cavities are then available for the adsorption of guest molecules. The micropore volume of, e.g., H-ZSM-5 ($SiO_2/Al_2O_3 = 75$) is 0.18 cm^3/g [42], and that of the NaA and NaX zeolites ($SiO_2/ Al_2O_3 = 2.5$), including the β-cages, is as high as 0.29 or 0.36 cm^3/g, respectively [5].

Densities also vary with the openness of the framework structure and the nature of the cations, generally lying in the range 1.9 – 2.3 g/cm^3. If the zeolite contains heavy cations such as Ba^{2+}, densities can be higher.

The surface selectivity of the zeolites as adsorbents depends on the SiO_2/Al_2O_3 ratio. Aluminum-rich zeolites preferentially adsorb strongly polar molecules, and are therefore widely used as drying agents (see Section 7.2). Increasing silicon content leads to increasingly hydrophobic character, the transition from hydrophilic to hydrophobic behavior occurring at a SiO_2/Al_2O_3 ratio of ca. 20 [38].

Due to the mobility of the cations in their cavities and channels, zeolites exhibit ionic conductivity [5, pp. 397 – 410], which depends on the diameter of the channels, the nature and concentration of the cations, and the water content. Control of these parameters and a wide range of other techniques enable the conductivity properties of zeolites to be modified to make them suitable for future use as solid-state electrolytes, membranes in ion-selective electrodes, and components of cathode materials in batteries [43], [44].

Chemical Properties. In spite of their open structure, the zeolites have remarkably good thermal stability, which varies with the structure type, but more so with the SiO_2/Al_2O_3 ratio and the nature of the cations. The effect of the SiO_2/Al_2O_3 ratio is illustrated by the example of faujasite. In a low-silica NaX zeolite ($SiO_2/Al_2O_3 = 2.5$), structural collapse was observed above 660 °C, while a structurally equivalent NaY zeolite ($SiO_2/Al_2O_3 = 5.0$) became amorphous above 700 °C [5, p. 495]. Highly dealuminated Y type zeolites, however, are structurally stable at >1000 °C [45]. The effect of the cation can be seen in zeolite A, the Ca form losing its structure above 700 °C, and the Na form above 660 °C [5, p. 495]. Above the decomposition temperature, recrystallization usually occurs, e.g., forming β-cristobalite (zeolite A) or a carnegieite phase (zeolite X).

The hydrothermal stability of the zeolites, i.e., the ability to retain their structure without undergoing a phase change in the presence of water vapor, is of practical importance. For example, FCC catalysts, which contain Y-type zeolites, are used in processes where steam is used to strip off adhering hydrocarbons [46]. The same factors that affect thermal stability also influence hydrothermal stability.

Strong acids decompose low-silica zeolites such as NaA and NaX by dissolving the aluminum atoms out of the framework, with consequent breakdown of the crystal structure [47]. With increasing SiO_2/Al_2O_3 ratio the zeolites become less sensitive to dealumination by acids (see Section 6.3.2); high-silica zeolites are structurally stable even in strong mineral acids [45].

Aqueous alkalis lead to phase transitions in high-aluminum zeolites. Thus, sodium hydroxide solution converts NaA zeolite into hydroxysodalite, which must be taken into account in production (see Section 6.2). Very high silica zeolites are dissolved by strong alkalis [48].

Suspensions of high-aluminum zeolites in which the cation is Na^+ have a pH of 9 – 12 due to partial hydrolysis.

(1)

The ion-exchange capacity of zeolites decreases with increasing SiO_2/Al_2O_3 ratio (see Sections 6.3.1 and 7.1). The catalytic properties of the hydrogen form, in which H^+ ions formally replace the metal ions, are discussed in Section 7.3.

4. Characterization

In principle, all methods used for investigating solids can be used for zeolites [49]. Moreover, the availability of modern physicochemical methods has significantly promoted the development of synthetic zeolites with tailored properties.

The size and shape of the zeolite crystals or aggregates must be investigated for most applications. This is carried out by microscopy, generally with a scanning electron microscope because of the small particle size. The particle size distribution can be rapidly determined by laser scattering or the Coulter counter method on zeolite suspensions.

The most important technique used to determine structure type and phase purity is X-ray diffraction (XRD). For known structures, a classification can be carried out by using the *Collection of Simulated XRD Powder Patterns for Zeolites* [50]. When structures of new materials are determined, the crystals available are seldom large enough for single-crystal X-ray structure analysis. Powder diffraction methods are therefore usual, sometimes with use of synchroton radiation [51]. The Rietveld method of profile analysis of the diffraction pattern has been developed into a very powerful tool [52]. XRD can only be used to estimate the fraction of crystalline material in a mixture with amorphous impurities in a zeolite sample by comparison with a standard material. This so-called crystallinity is usually determined by comparing the intensities of selected reflections [53].

The thermal stability of zeolites can be determined by XRD or differential thermal analysis.

Zeolites can be analyzed for elements by classical wet chemical methods, but modern physical methods are usually preferred, i.e., X-ray fluorescence analysis (XRF), atomic absorption spectrometry (AA), and inductively coupled plasma spectrometry (ICP). X-ray photoelectron spectroscopy (XPS) is particularly useful for obtaining information about the composition of the outer atomic layers of a zeolite crystal.

The determination of the SiO_2/Al_2O_3 ratio of zeolites is of importance in many of their applications [54]. While the SiO_2/Al_2O_3 ratio of the bulk sample can easily be analyzed by the above-mentioned methods, more detailed information can be obtained by high-resolution magic angle spinning NMR spectroscopy. Thus ^{29}Si MAS-NMR spectroscopy is very suitable for determining the SiO_2/Al_2O_3 ratio of the zeolite framework, especially if the sample also contains aluminum that is not part of the framework. ^{29}Si and ^{27}Al MAS-NMR spectroscopy also gives important information on the short-range structural environment of the silicon and aluminum atoms [55–57]. Thus, the five groups $Si(OSi)_{4-n}(OAl)_n$ ($n = 0-4$) give signals with different chemical shifts in the ^{29}Si MAS-NMR spectrum. In the ^{27}Al MAS-NMR spectrum, aluminum atoms in different states of coordination give separate signals. In zeolites of the faujasite type, the SiO_2/Al_2O_3 ratio can also be estimated from measurements of the crystallographic unit cell [58] and from the position of the framework-vibration bands in the IR spectrum [59].

Information about the characteristics of the pore system can be obtained from adsorption measurements. The size of the apertures can be estimated by testing their accessibility to adsorptives of various kinetic diameters. However, determination of the inner surface area and the micropore volume from the adsorption and desorption isotherms of nitrogen is problematic [60]. ^{129}Xe MAS-NMR spectroscopy is a relatively new method of investigating the cavity systems in large-pore zeolites, the adsorbed xenon atoms acting as probes [61]. Test catalytic reactions, the outcome of which depends on the shape selectivity of the zeolite (see Section 7.3), can also be used to characterize pore systems. Depending

on the reaction, the characteristic value obtained is known as the constraint index, the modified constraint index, or the spaciousness index [62].

In the development of zeolite catalysts, it is also important to characterize their acidity properties, i.e., the nature, number, and strength of the acid sites [49], [63]. Methods include temperature-programmed desorption (TPD) of adsorbed bases such as ammonia and pyridine, ^{1}H MAS-NMR spectroscopy [64], IR spectroscopy in the region of O – H stretching frequencies [65], and measurement of the catalytic activity of the zeolites in standard reactions [63].

In addition to these general methods of investigation, zeolites are also characterized in industry by parameters that relate to a particular application. For example, where zeolites are used as detergent builders, these can include calcium binding power (determined by titration) and whiteness [66]. The suitability of a zeolite as a catalyst is determined by testing it in the reaction concerned [67].

5. Natural Zeolites

5.1. Occurrence, Mining, and Processing

Zeolite minerals occur in many rocks on the earth's surface and on the sea bed. They were first discovered in crevices and cavities in basalt flows, where they were formed by the hydrothermal decomposition of the magmatic rock. It was only in the mid-1900s that zeolites were found to occur in enormous quantities as sedimentary rock. These zeolitic tuffs were formed during various geological periods, mainly by the action of water on volcanic ash. Zeolites were also formed from poorly crystalline clays, biogenic silica, feldspars, and feldspathoids. Moreover, the less stable types of zeolite formed during the initial crystallization changed into more stable types, e.g., phillipsite or clinoptilolite in analcime.

The formation of zeolites was influenced by many specific local conditions that had to be favorable: temperature (usually in the range 25 – 50 °C), pressure, pH, type and concentration of salts, and availability and reactivity of silicon and aluminum sources. Suitable conditions arise in various geological or hydrological systems, which can be open or closed [17–19], [68]. Thus, zeolites occur in deposits formed from lakes with high salt or alkali contents in arid and semiarid regions. Here, dissolved sodium carbonate/sodium hydrogencarbonate can cause the pH to reach ca. 9.5. Zeolites have also been formed in alkaline soils on the earth's surface and in ocean sediments as a result of the action of percolating water, hydrothermal activity, and burial diagenesis. Depending on the system, a characteristic series of deposits varying in composition, thickness, and extent is formed. The zeolite-containing layers can be several hundred meters in depth, and can extend over areas of hundreds of square kilometers.

Of the 40 zeolitic minerals discovered in nature, clinoptilolite [*12173-10-3*] and the structurally related heulandite, mordenite [*12173-98-7*], phillipsite, chabazite [*12251-32-0*], erionite, analcime, and laumontite occur in the largest quantities. However, only the first six of these materials are of commercial importance at present. Information on the structures and composition ranges of these zeolites is given in Table 2.

Natural zeolites are mined in the western United States, Cuba, Japan, Slovakia, Hungary, Serbia, Bulgaria, Italy, Germany, and the CIS states, mainly by the open-cast method. Depending on the deposit, zeolites can contain other minerals as impurities, e.g., montmorillonite, cristobalite, quartz, biotite, and potassium feldspar. Mixtures of different zeolites often occur. Zeolitic minerals are processed by crushing, grinding, and classification. If they are to be used as fillers in the paper industry, wet chemical bleaching is also necessary [69].

5.2. Commercial Applications and Importance

The consumption of clinoptilolite, which has a wide range of uses, far exceeds that of any other natural zeolite [19], [70], [71]. For example, it is used in agriculture as an animal feed additive and for soil improvement (mainly in Japan). The latter application depends on two effects: it increases the pH of the soil, and, being an ion exchange material, it stores ammonium and potassium ions, thereby prolonging the activity of fertilizers. The ability to take up ammonium

Table 2. Structures and compositions of some important natural zeolites

Zeolite	Structure type [28] (dimensionality of pore system)	Window	SiO_2/ $[Al_2O_3 + Fe_2O_3]$	Most common cations	Typical composition of unit cell
Clinoptilolite	HEU (3)	8-/10-/8-ring	8.0 – 10.2	K > Na	$(Na,K)_6[(AlO_2)_6(SiO_2)_{30}] \cdot 24\,H_2O$
Heulandite	HEU (3)	8-/10-/8-ring	5.8 – 8.0	Ca, Na	$Ca_4[(AlO_2)_8(SiO_2)_{28}] \cdot 24\,H_2O$
Mordenite	MOR (2)	12-/8-ring	8.6 – 10.6	Na > K	$Na_8[(AlO_2)_8(SiO_2)_{40}] \cdot 24\,H_2O$
Phillipsite	PHI (3)	8-/8-/8-ring	2.6 – 6.8	K, Na, Ca	$(Ca,K_2,Na_2)_3[(AlO_2)_6(SiO_2)_{10}] \cdot 12\,H_2O$
Chabazite	CHA (3)	8-ring	3.4 – 7.6	Ca, Na, K	$Ca_6[(AlO_2)_{12}(SiO_2)_{24}] \cdot 40\,H_2O$
Erionite	ERI (3)	8-ring	6.0 – 7.0	K, Mg, Ca, Na	$(Ca,Mg,Na_2,K_2)_{4.5}[(AlO_2)_9(SiO_2)_{27}] \cdot 27\,H_2O$

ions is also the reason for the use of clinoptilolite and phillipsite in fish farming and cat-litter production.

If high purity, constant composition, and high capacity are not essential, natural zeolites can compete with their synthetic counterparts in a number of industrial applications. Examples include the drying of gases or liquids with clinoptilolite tuffs, and the selective adsorption of CO_2 and SO_2 by clinoptilolite or mordenite. In these applications, the stability of these zeolites towards acids is advantageous. Clinoptilolite is also sometimes used for decontaminating radioactive wastewater because of its selectivity for ^{90}Sr and ^{137}Cs ions [19], [70–72]. Natural zeolites are also used as fillers in paper and plastics, and as constituents of pozzalanic cements and lightweight building blocks.

The quantities of natural zeolites mined worldwide and the total consumption can be estimated only approximately. A figure of ca. 300 000 t/a is realistic. Japan consumes the major proportion of this, i.e., currently 130 000 t/a, while consumption in western Europe and the United States is comparatively low, namely 25 000 t/a and 15 000 t/a, respectively.

6. Production of Synthetic Zeolites

The methods used in the industrial production of solids are always influenced by the specific requirements associated with the eventual use of such materials. As this also applies to zeolites, it is normally not enough to synthesize a single-phase microcrystalline zeolite powder of definite chemical composition. Other properties are also important, such as crystallite size and morphology. Moreover, for many applications, the as-synthesized zeolite must be chemically modified by processes such as ion exchange or dealumination. Finally, for most applications in adsorption and catalysis, shaped products are required. These usually contain binders, which can impart additional properties to the product. The manufacturing of a zeolite product therefore includes much more than the actual zeolite synthesis, and consists of a well-defined series of individual steps aimed at providing a specific spectrum of tailored properties.

6.1. Zeolite Synthesis: Routes and Raw Materials

Synthetic zeolites are produced under conditions similar to those that led to formation of natural zeolites, i.e., by the mineralizing effects of water and OH^- ions on reactive sources of silica and alumina in the presence of cations. However, the time required for formation of zeolites is shortened by using considerably higher temperatures and pH values. For example, high-silica zeolites are synthesized under hydrothermal conditions at temperatures exceeding 100 °C and at high pressure [73], while low-silica zeolites are usually crystallized at 70 – 100 °C [5], [11]. The pH is usually in the range 10 – 14. Reactive precursors for zeolite formation are mainly silica – alumina hydrogels produced in situ, although clay minerals are also used.

The composition of the reaction mixture is of vital significance for the synthesis process. This is usually expressed as the oxide ratio $a\,M_{2/n}O : Al_2O_3 : b\,SiO_2 : c\,R : d\,H_2O$, in

which M represents cations with charge n, and R is an organic template compound. Such compositions describe a synthesis field and lead to a specific zeolite type. Synthesis fields are often represented in a triangular diagram of the system $M_{2/n}O - Al_2O_3 - SiO_2$ (Fig. 4).

Figure 4. Synthesis fields
$a\,Na_2O : b\,Al_2O_3 : c\,SiO_2 : (90-100)\,H_2O$ for various zeolites (HS = hydroxysodalite) at a crystallization temperature of 100 °C
Points marked with asterisks indicate typical compositions of the products.

6.1.1. Synthesis from Gels

In the synthesis of zeolites from hydrogels, the composition of the reaction mixture is not the only important factor. The selection of the raw materials, the way in which the reactants are mixed to precipitate the gel, and its aging influence the course and rate of the subsequent zeolite crystallization and properties of the product, such as crystal morphology.

Various silica and alumina sources can be used as raw materials. In industrial production, the cost is an important consideration apart from the fundamental suitability of the materials.

The main silica sources used for the large-scale production of zeolites are sodium silicate solutions and precipitated amorphous silicas. Silica-containing waste products from large-scale industrial processes, e.g., blast furnace slags or fly ash, have the disadvantage that they are usually contaminated with heavy metals which to some extent enter the zeolites produced. For the synthesis of expensive specialty zeolites, pyrogenic silica, colloidal silica, and esters of silicic acid such as tetraethoxysilane are used. The most common alumina source is sodium aluminate.

A further reactant is also necessary that provides OH^- ions. Sodium hydroxide solution is used except for those few cases in which the presence of Na^+ ions prevents the formation of the desired zeolite type. Alternatively, the function of the OH^- ion as a mineralizer can be performed by the fluoride ion, as has been demonstrated in a number of zeolite syntheses [74].

The synthesis of high-silica specialty zeolites often has to be carried out in the presence of organic templates. These can be alkylammonium salts, alkylammonium hydroxides, amines, alcohols, or ethers [75], [76]. The function of these additives in zeolite syntheses is not yet fully understood. A purely template effect can be excluded in syntheses in which completely different agents lead to the same structure type [76]. Often the template molecules or ions simply seem to act as space fillers. The metal cations (usually Na^+) in the reaction mixtures can also be assumed to exhibit a structure-directing effect.

The formation of zeolites from the hydrogel that is formed by bringing together the above components is a very complex process, all details of which are not completely understood. However, the following concept is generally accepted [11], [77–80]: The gel partially dissolves during the aging process and especially when the temperature is raised to initiate zeolite crystallization. The liquid phase present with the gel becomes supersaturated, first with monomeric silicate, and then with oligomeric silicate species and aluminosilicate building blocks. The state of supersaturation ends with the formation of seeds of a metastable zeolitic phase. These then grow to form crystals.

Factors affecting the rate of zeolite formation include the reactivity of the gel, the pH, and the temperature. Increase in pH and temperature leads to increase in the rate of formation of zeolite crystals. However, the resulting zeolitic phases are metastable in their mother liquors, and the zeolite initially formed may undergo a transformation into an undesired thermodynamically more stable phase. A typical example is the formation of hydroxysodalite from NaA ze-

olite. The rate of synthesis of the zeolite can also be controlled by addition of seeds [11], [81].

6.1.2. Synthesis from Clay Minerals

Clays can also be suitable raw materials, especially for the production of the zeolites NaA, NaX, and NaY [5], [11]. The iron content of these natural materials should be as low as possible. The most important clays for zeolite production are kaolin and metakaolin, the latter being obtained by calcining kaolin at 500 – 700 °C. On further heating, spinel is formed at >980 °C and mullite at >1050 °C, with formation of silica-rich phases.

$$\underset{\text{Kaolin}}{2\,Al_2Si_2O_5(OH)_4} \rightarrow \underset{\text{Metakaolin}}{2\,Al_2Si_2O_7} + 4\,H_2O \qquad (2)$$

To produce zeolite NaA, sodium hydroxide is also required, and to produce silica-rich faujasites, further SiO_2 equivalents (e.g., sodium silicate).

The synthesis of zeolites from kaolin or metakaolin is of industrial interest because its allows production of binder-free extrudates and granules (see Section 6.3.4). These shaped materials consist entirely of active substance, which is an advantage in adsorption technology. Various methods for achieving this have been described. For example [82], [83], kaolin or metakaolin is first shaped, and SiO_2 and seed crystals are added, depending on the zeolite. The zeolite is then crystallized while in the preformed shape. Alternatively, metakaolin is used as the binder as the zeolite is formed, and the binder component is then converted into zeolite by hydrothermal treatment with sodium hydroxide solution [84], [85].

In-situ production of FCC catalysts from kaolin is of major importance. The process, developed by Engelhard, has many variations [86–88]. The products are NaY zeolites in a matrix that is enriched in Al_2O_3 compared with the raw material kaolin. In one variation, microgranules containing >40 % type Y zeolite are obtained [88]. For this, a slurry containing kaolin tempered at ca. 980 °C, water-containing kaolin, sodium silicate, and zeolite seed crystals is first spray dried, and the microgranules formed are calcined at ca. 750 °C, converting the watercontaining kaolin into metakaolin. The matrix-bonded NaY zeolite is then formed by treatment with sodium hydroxide and sodium silicate at 98 °C. This is followed by the process that generates the active catalyst, e.g., ion exchange or ultrastabilization (see Sections 6.3.1 and 6.3.2). Thus, in contrast to other processes, the zeolite component of the catalyst is not synthesized separately.

6.2. Examples of Industrial Zeolite Syntheses

The processes and potential problems in the industrial production of zeolites [5], [89–91] are illustrated here by the syntheses of the commerically important zeolites NaA, NaY, and Na-ZSM-5.

Figure 5. Electron micrograph showing crystals of detergent NaA zeolite

Zeolite NaA [*68989-22-0*] is mainly used directly as a detergent builder, but is also a starting material for the production of a wide range of adsorbents (see Sections 7.1 and 7.2). An NaA zeolite detergent builder should have the following properties: high ion-exchange capacity (>160 mg CaO/g dry weight at 20 °C) [66] with the ability to bind ions (especially Ca^{2+}) rapidly, good dispersibility, low tendency of suspensions to settle out, low abrasive properties, and good whiteness. This means that the zeolite must consist of a single phase, as the presence of impurities such as hydroxysodalite, which forms readily along with NaA, reduces the ability of the product to bind Ca^{2+} ions. Furthermore, the average particle size must be <4 μm and the zeolite

crystals must not have sharp corners or edges. A scanning electron micrograph of a materials of this type is shown in Figure 5.

In the Degussa [92], Henkel [93], [94], and PQ processes, such a zeolite is synthesized by reacting sodium silicate containing various amounts of Na_2O and SiO_2 with sodium aluminate solutions. Clays are less often used, as the presence of impurities, especially iron, can impart an undesirable color to the product. A special variation is the Mizusawa process in which an acid-treated clay is used [95].

In the production of zeolite NaA, the stoichiometry of the reaction mixture can in principle be varied over a relatively wide range. However, efficient production requires optimization of the composition from the point of view of product quality, yield, and reaction time. A possible stoichiometry is $3.4\,Na_2O : Al_2O_3 : 1.8\,SiO_2 : 90\,H_2O$ [93]. In this example, an excess of aluminum compared with the product stoichiometry ($SiO_2/Al_2O_3 = 2.0$) is used.

Figure 6 is a flow diagram of a process for the production of this zeolite [96]. Gel precipitation and aging are usually carried out at 50 – 70 °C. Gel precipitation is generally a batch process, but it can also be carried out continuously [94]. However, the subsequent crystallization at 80 – 90 °C is a batch operation in stirred vessels, often $>100\,m^3$ in volume. Under these conditions, the zeolite is present in crystalline form after ca. 1 h. The suspension formed contains 120 – 200 kg zeolite (dry basis)/m^3. The product is recovered and washed on a filter press, rotary filter, or band filter. The filter cake is slurried in water and, after the addition of stabilizers to prevent rapid sedimentation, is usually supplied to the detergent manufacturer in this form. The products are obtained in powder form by spray drying the zeolite suspension or by directly drying the zeolite filter cake.

Both the mother liquor from zeolite crystallization and the wash water are alkaline as they contain residual sodium hydroxide. If an excess of Al_2O_3 is used, sodium aluminate is also present. In this case, the filtrate is concentrated by evaporation and recycled.

The particle size, a critical parameter when the product is used as a detergent builder, is influenced by the Na_2O/H_2O ratio in the reaction mixture. High basicity favors the formation of small particles [97]. The sequence of addition of the various components and the rate of addition during gel preparation also exert an influence. Other factors include temperature and method of stirring, especially during gel formation, and use of seed crystals [89].

Figure 6. Process for the preparation of NaA zeolite [96] a) Silica – alumina hydrogel precipitation; b) Zeolite crystallization; c) Filtration; d) Mother liquor evaporation; e) Zeolite spray drying; f) Stabilized suspension of NaA zeolite

Zeolite NaY is the basis for the zeolite components of FCC and hydrocracking catalysts (see Section 7.2). This raw material must have high phase purity and good crystallinity. The SiO_2/Al_2O_3 ratio should be as high as possible, as type Y zeolites modified for catalytic purposes must have good thermal and hydrothermal stability.

Commercially available NaY zeolites have an SiO_2/Al_2O_3 ratio of 5.0 – 5.6. In principle, materials with higher SiO_2 content can be produced by direct synthesis, but the

necessary reduction of the Na_2O/SiO_2 and Na_2O/H_2O ratios in the reaction mixture lead to a drastic increase in crystallization time, so that such syntheses are not economic [98], [99]. Reaction mixtures with composition (2.5 – 3.5) Na_2O : Al_2O_3 : (8.0 – 10.0) SiO_2 : (120 – 180) H_2O are usually used for industrial production of NaY zeolite. The various synthetic and mineral raw materials are described in Sections 6.1.1 and 6.1.2.

Figure 7. Process for the production of NaY zeolite [103] a) Zeolite synthesis (gel precipitation, aging, crystallization); b) Zeolite filtration; c) Zeolite storage; d) Mother liquor and wash water storage; e) Silica – alumina hydrogel formation; f) Silica – alumina hydrogel filtration and washing; g) Silica – alumina hydrogel slurry storage

In early syntheses of NaY zeolite, the gel initially precipitated had to be aged for one or more days at room temperature. Today, seeding mixtures are generally added instead, often in colloidal form [100], [101]. They have compositions in the range (10 – 16) Na_2O : Al_2O_3 : (10 – 16) SiO_2 : (180 – 320) H_2O and strongly influence the rate of crystallization.

The temperature during crystallization is 85 – 100 °C. Depending on this and on the composition and nature of the gel, a well-crystallized NaY zeolite can be obtained in 12 – 24 h. In some cases, vigorous stirring can lead to the formation of gmelinite and phillipsite as foreign phases. Ifthe heating time is too long, this can cause transformation into more thermodynamically stable zeolites of the P or cancrinite type [102].

Figure 7 is a schematic flow diagram of a process for the production of NaY zeolite [103]. Characteristic of this process is the work-up of the mother liquor, which in the case of the synthesis of NaY zeolite is a dilute solution of sodium silicate.

ZSM-5 [*79982-98-2*]. As the SiO_2/Al_2O_3 ratio of ZSM-5 can vary over a wide range (see Table 1), ZSM-5, first synthesized by Mobil [104], is not a single material, but a family of zeolites of the MFI structure type [28]. The synthesis of these compounds differs from that of NaA and NaY zeolites mainly in that it is carried out at 120 – 180 °C in pressure vessels. ZSM-5 can be crystallized with or without template compounds [40], [73], [104–106]. Tetrapropylammonium salts are mainly used as template, but hexamethylenediamine and a series of other compounds are also suitable [75], [76]. However, the ranges of SiO_2/Al_2O_3 ratios achievable in the product by varying the initial stoichiometry by the two methods are not identical. Thus, without a structure-directing agent, SiO_2/Al_2O_3 ratios between ca. 25 and 100 can be obtained, while with template compounds a significantly wider range can be covered, i.e., from ca. 30 to the aluminum-free form (silicalite-1). Moreover, depending on the raw materials used and the exact synthesis conditions, the crystal morphology and distribution of the aluminum atoms over the crystal cross section can vary greatly [40], [73]. These parameters are of major importance in the use of ZSM-5 zeolites in catalysts.

The composition 17.1 $(TPA)_2O$: Na_2O : Al_2O_3 : 27.7 SiO_2 : 453 H_2O is a typical example of a synthesis mixture for which tetrapropylammonium bromide (TPABr) is used as the template. After 5.5 d at 125 °C, this gives ZSM-5

with a SiO_2/Al_2O_3 ratio of ca. 45 [104]. In contrast, the synthesis mixture 11.2 $Na_2O : Al_2O_3 : 70\,SiO_2 : 3213\,H_2O$, without a template and using colloidal silica as the source of silica, gives a zeolite with an SiO_2/Al_2O_3 ratio of 44 after 24 h at 190 °C [105].

The crystal suspension obtained is worked up as described above for NaA and NaY zeolite. If an organic template compound is used, it must be calcined from the ZSM-5 pores by heating to ca. 650 °C in air.

6.3. Modification and Formulation

The hydrothermal synthesis step described in Sections 6.1 and 6.2 establishes the structure type of the zeolites and the size and shape of their crystals. Only detergent zeolites are in their final form at this stage. For use as a catalyst or adsorbent, their properties must be fine tuned. This is mainly performed by ion exchange and dealumination. In addition the properties of zeolites are modified by forming them into shapes appropriate for the flow conditions under which they will be used.

6.3.1. Ion Exchange

In the production of zeolitic adsorbents, the most important techniques for increasing or decreasing the apparent pore diameter ("pore-size engineering") are those involving ion exchange [5]. An important example is the exchange of sodium ions in zeolite NaA with calcium or potassium ions. After partial replacement of ca. 30 % of the Na^+ ions by Ca^{2+}, a sudden "dilation" of the pore openings from ca. 0.38 nm (4A type [*70955-01-0*]) to 0.43 nm (5A type [*69912-79-4*], [*68989-20-8*]) is observed. Conversely, the replacement of ca. 25 % of the Na^+ ions by K^+ causes "narrowing" of the windows to ca. 0.30 nm (3A type [*68989-21-9*]).

Ion exchange is also important in the synthesis of zeolite catalysts. The aim is usually to produce Brønsted acid sites, as zeolites act as solid acids in catalysis (see Section 7.3). For certain intermediate-silica and high-silica zeolites (e.g., mordenite), the necessary ion exchange can be achieved by treatment with mineral acids. However, this method also involves the risk of dealuminating the zeolite framework (see Section 6.3.2), and many high-aluminum species such as NaY zeolite lose their crystal structure, at least partially, at higher acid concentrations [47]. Therefore, an indirect route via an ion exchange with ammonium salt solutions must be followed. This produces the "ammonium form", which is calcined at ca. 400 °C to liberate ammonia and give the hydrogen form. In the case of zeolite Y, an acid form is also obtained by incorporating polyvalent cations, especially of rare earth metals, by ion exchange (see Section 7.3).

In the production of bifunctional zeolite catalysts that combine acidity with hydrogen-transfer capability, the inclusion of metals such as palladium and platinum is important. The first step is ion exchange with $[Pd(NH_3)_4]^{2+}$ or $[Pt(NH_3)_4]^{2+}$. The chemistry of Pd^{2+} and Pt^{2+} in zeolitic pores has been thoroughly investigated, especially in the case of zeolite Y. Calcination in the presence of oxygen to destroy the ligands followed by a heat treatment in a hydrogen atmosphere leads to formation of metal clusters of various sizes, locations, and states of dispersion, depending on the exact conditions [107], [108].

In the most widely used ion-exchange process, zeolites are treated with aqueous solutions that contain the cations to be introduced. Solid-state ion exchange in which the zeolites, usually in the ammonium or hydrogen form, are heated with crystalline salts, is as yet rarely used in industry [109], [110]. Ion exchange also occurs on impregnating zeolites with solutions of metal salts.

The equilibria and kinetics of ion exchange with zeolites in aqueous suspension are complex subjects in which several factors interact [5], [72], [111].

The theoretical maximum ion-exchange capacity of a zeolite is determined by its SiO_2/Al_2O_3 ratio. The true or maximum attainable ion-exchange capacity to be expected in a given case is influenced by ion-sieve and volume effects. For example, the pore apertures of zeolite X (crystallographic diameter 0.74 nm) do not permit penetration of $[N(C_2H_5)_4]^+$ ions (diameter 0.80 nm) into the cavity system. Metal cations with large, strongly bonded hydration shells such as Li^+ and Mg^{2+} cause similar problems. Nevertheless, slow ion exchange is possible in these cases, for which the cation has to

"cast off" the coordinated water molecules, at least partially. However, even in the case of wide pore apertures cations that are large in the unhydrated state still give low rates of ion exchange. The space requirements of these cations in the cavities and the need to balance the charge of the framework are then in opposition to each other.

In addition, a sieve effect within the zeolite framework can occur if the cations being exchanged are located in small and inaccessible cages. An important example of this is provided by the faujasites, in which the Na^+ ions located in the sodalite cages cannot be replaced by larger cations under mild conditions. Hence, the maximum achievable degree of exchange with rare earth cations for zeolite NaY at 25 °C is only ca. 70 % [112]. This exchange is of importance in the production of FCC catalysts (Section 7.3). It can only be carried out to completion at 180 °C under pressure. However, a different method is usually used: After achieving the degree of exchange attainable under mild conditions, the zeolite is calcined at ca. 350 °C. This causes the Na^+ ions to migrate out of the sodalite cages into the supercages where they are replaceable, and a further treatment of the zeolites with rare earth salt solutions enables exchange to be completed. The same method can be used for ammonium ion exchange [113].

In general, the ion exchange reaction for two cations A and B with charges n_A and n_B is represented by Equation (3). The symbols (z) and (s) indicate whether the cation is in the zeolite phase or in aqueous solution. The position of the equilibrium is a measure of the ion-exchange selectivity. The selectivity for given cations is determined by the electric fields of the coordinating anionic locations in the zeolite framework. Thus, for each zeolite type there is a specific selectivity series with the cations arranged in order of increasing exchangeability [5], [114].

$$n_A B^{n_{B^+}}\,(z) + n_B A^{n_{A^+}}\,(s) \rightleftharpoons n_A B^{n_{B^+}}\,(s) + n_B A^{n_{A^+}}\,(z) \qquad (3)$$

The selectivity of an ion-exchange process involving a given cation pair is illustrated by isotherms in which the equivalent fraction of the entering cation A in solution A_s is plotted against the equivalent fraction for the same cation in the zeolitic phase A_z [5], [111], [115]. The isotherms describe the situation after equilibrium has been reached. Figure 8 shows examples of isotherms for several cations in the ion-exchange reaction on the zeolite NaA (B = Na^+). For A = Ag^+, Ca^{2+} there is selectivity in favor of the added ions, whereas if A = Li^+ the equilibrium of Equation (3) always lies on the left-hand side. For A = K^+, the selectivity varies with the extent of ion exchange.

Figure 8. Ion-exchange isotherms for Li^+, K^+, Ag^+, and Ca^+ on zeolite NaA at 25 °C
Total concentration in aqueous phase: 0.1 N

Another important parameter is the pH of the exchange solution. At low pH values, H_3O^+ ions compete with the metal cations for the exchange locations. The pH must also be considered when ion exchange takes place with highly charged transition metal cations such as Fe^{3+} or Cu^{2+}, as an acidic medium is necessary here to prevent precipitation of metal hydroxides. However, slurries of low-silica zeolites such as A or X are alkaline, and these materials are unstable at low pH (see Section 3.2). These problems can often be overcome by the use of complex cations (e.g., ammine complexes).

In industry, there are many methods of carrying out an ion-exchange reaction in aqueous solution. The simplest is to suspend the zeolite in the solution under the appropriate conditions for ion exchange (amount and concentration of the salt, temperature, and pH). This is followed by filtration and washing of the filter cake. A more elegant technique is to combine these steps in a continuous process, whereby ion exchange and

washing are carried out on a band filter, for example.

A process of this kind often needs to be repeated to obtain the desired extent of ion exchange. In these cases, a process with countercurrent flow of the components is more efficient and economic [116]. The solid and the salt solution are fed in opposite directions, so that fresh unreacted zeolite comes into contact with a solution that has already been used to treat partly ion exchanged material and is therefore partially depleted in the cations to be introduced.

6.3.2. Dealumination

Dealumination increases the SiO_2/Al_2O_3 ratio of zeolites. The term is usually understood to mean the removal of aluminum from the zeolite framework, even where the overall composition of the material is unaltered or only slightly altered because the aluminum removed from the framework remains in the channels and cavities.

Dealumination is mainly carried out on zeolites with an intermediate SiO_2/Al_2O_3 ratio (see Section 3.2) that cannot be directly produced in a high-silica form and have sufficient stability to survive the sometimes drastic treatment without appreciable loss of crystallinity. The prototype for the development of dealumination methods was zeolite Y, as both its hydrothermal stability can be considerably increased and its catalytic activity for use in FCC catalysts can be modified by dealumination [45], [86], [117]. Mordenite is also often modified by dealumination [118], [119]. Dealumination is rarely used for zeolites such as ZSM-5, which can be obtained directly as a high-silica molecular sieve by hydrothermal synthesis. The catalytic properties of high-silica materials synthesized by dealumination are expected to differ from those of zeolites with the same SiO_2/Al_2O_3 ratio produced directly, as the dealumination of the structure can lead to the production of crystal defects, creation of a secondary pore system, and formation of nonframework aluminum.

A range of chemical methods [45], [117] are available for dealumination of zeolites, some of which are practiced on an industrial scale.

The simplest method is to extract aluminum with a mineral acid. This is often carried out with mordenite, which is usually produced in the Na form with an SiO_2/Al_2O_3 ratio of 10 – 12 [118], [119]. Depending on the reaction conditions, a high-silica material with a low cation content is obtained. In the case of zeolite Y, obtainable with an SiO_2/Al_2O_3 ratio of up to 6.0 by direct synthesis, this method, which causes defects, leads to considerable destruction of the framework structure. For this zeolite, the process is only suitable when used in conjunction with preliminary dealumination by another method in which not only aluminum is dissolved out of the framework but also some isomorphic replacement of aluminum by silicon takes place.

Of these methods, the steaming of Y zeolites in the NH_4^+ form (residual content of Na_2O <3 – 4 %) is of the greatest importance. Industrially, this is carried out at 600 – 800 °C in rotary kilns [46], [86], [87]. This causes aluminum atoms to migrate from the framework into the cavities, forming nonframework species. In principle, this process is a high-temperature hydrogenolysis of Si – O – Al bonds. The process causes limited damage to the structure, which can be detected by the formation of mesopores. The resulting holes are partially filled by silicon atoms from amorphous SiO_2 originating from destroyed crystal domains. The resulting zeolites have a framework structure with an increased SiO_2/Al_2O_3 ratio and very good thermal and hydrothermal stability. Today, they are of major importance as components of FCC catalysts, and are known as ultrastable Y zeolites (USY zeolites, see Section 7.3). Additional stabilization is obtained by subsequent exchange of the residual Na^+ ions with NH_4^+ ions. Nonframework aluminum species can be removed by washing with solutions of acids or alkalis [45].

In a Degussa process [120], [121], NaY zeolite is dealuminated by complete isomorphic replacement of aluminum atoms by silicon atoms using gaseous silicon tetrachloride at 250 – 500 °C. The reaction product $NaAlCl_4$ is removed from the cavities by washing with water. Depending on the temperature used, low-defect Y zeolites with various degrees of dealumination can be obtained. In particular this method offers a direct route to materials with SiO_2/Al_2O_3 ratios of 200 or more. These are extremely hydrophobic and are used for waste-air and exhaust gas purification (see Section 7.2). In contrast to zeolite Y, it is very difficult to

dealuminate mordenite with silicon tetrachloride [118].

Another isomorphic replacement technique is to react ammonium-exchanged Y zeolites with an aqueous solution of ammonium hexafluorosilicate [122], [123], producing thermally and hydrothermally stable Y zeolites with SiO_2/Al_2O_3 ratios of up to ca. 20. These are mainly used in FCC catalysts. Equations (4) and (5) represent the two methods, idealized for a Y zeolite with a SiO_2/Al_2O_3 ratio of 5.0.

$$Na_{55}[(AlO_2)_{55}(SiO_2)_{137}] + y\,SiCl_4 \rightarrow Na_{55-y}[(AlO_2)_{55-y}(SiO_2)_{137+y}] + y\,NaAlCl_4 \quad (4)$$

$$(NH_4,Na)_{55}[(AlO_2)_{55}(SiO_2)_{137}] + y\,(NH_4)_2SiF_6 \rightarrow (NH_4,Na)_{55-y}[(AlO_2)_{55-y}(SiO_2)_{137+y}] + y\,(NH_4)_3AlF_6) \quad (5)$$

Other dealumination processes [45], [117], involving, e.g., the use of F_2, $CrCl_3$, or H_4EDTA, are not of industrial importance.

6.3.3. Other Methods of Zeolite Modification

Other less industrially important methods are known in addition to those described in Sections 6.3.1 and 6.3.2. The silanization of zeolites with mono- and disilane and the chemisorption of diborane have been thoroughly investigated. These lead to a narrowing of the pore system and to changes in the selectivity of the interior surfaces [124]. Reaction with tetraalkoxysilanes followed by calcination in the presence of oxygen only reduces the size of the pore apertures [125].

In an alternative method to ion exchange, transition metals can be introduced into the pore systems of zeolites by means of organometallic complexes [126]. In particular, socalled "ship-in-a-bottle" phthalocyanine complexes can be synthesized directly in the cavities [127].

6.3.4. Shaping

Various industrial operations for shaping other powdered materials [128–130] are also used for shaping zeolites for use as catalysts and adsorbents. These include extrusion, and granulation by the granulating pan, fluidized-bed, and spray methods. The choice of method depends on the size and geometry most suitable for a particular application. Shaping is usually followed by drying and calcination.

To give the shaped bodies adequate mechanical stability, binders must be added to the zeolite powders. These can consist of clays such as kaolins and bentonites or synthetic materials such as amorphous silica, alumina, and silica – alumina gels. Substances that act as sources of silica, e.g., silica sols or, more rarely, esters of silicic acid, are also used in the shaping process. Binder-free shaped zeolite bodies in which the binders are transformed into zeolitic phases are a special case (see Section 6.1.2).

The selection of the type and quantity of binder must take account of the fact that the matrix in which the zeolite crystals are embedded may perform a large number of other functions in addition to its primary function, and that these may have an important effect on the property profile of the zeolitic catalysts and adsorbents. Thus, the matrix may "dilute" the activity of the zeolite, but may actually contribute to the activity of the catalyst. It can also act as a sink for sodium or vanadium ions, increasing thermal and hydrothermal stability in the case of FCC catalysts [86].

When NaA zeolite powder is granulated with water glass, the latter adheres to the pores to some extent [91], [131], leading to a reduction in the apparent pore size to ca. 0.30 nm. This effect is essential if the granulate is to be used as a drying agent in insulating glass (double glazing) (see Section 7.2).

The macroporosity of the shaped body can be influenced by the addition of certain organic compounds such as melamine. These are burnt off in a subsequent calcination stage [130].

6.4. Environmental Aspects

In the industrial-scale production of zeolites such as NaA and NaY, substances present in the mother liquors are recycled to the synthesis process (production-integrated environmental protection). The use of template compounds in the production of specially zeolites presents greater problems. The tetraalkylammonium salts and organic amines which are often used are very difficult to destroy by oxidation in the mother liquor.

There are therefore ecological as well as economic reasons to minimize the amounts of these compounds used in the synthesis.

The same is true of the metal salts used in ion-exchange processes. Here, judicious operation can be of benefit in a multistage process [116]. Dilute solutions of ammonium salts, e.g., those produced during the conversion of zeolites into the catalytically active hydrogen form, can be treated in various ways [132].

7. Applications of Synthetic Zeolites

7.1. Ion Exchange: Zeolites as Detergent Builders

The most important use of synthetic zeolites based on their ion-exchange properties is as builders in detergents. This is the largest single application of zeolites (see Chap. 8). The removal of undesired ions from wastewater is mainly carried out with the comparatively cheap natural zeolites (see Section 5.2). The treatment of wastewater from the electroplating industry with powdered NaA zeolite is an exception [133].

Pentasodium tripolyphosphate (STPP) was long regarded as the best builder for detergents on account of its excellent sequestering powers for calcium and magnesium ions and its outstanding ability to disperse soil particles. However, an intensive search for alternatives began in the early 1970s. This was driven by the discovery that a high proportion of the phosphate pollution in stationary or slow-moving natural surface waters in industrialized countries was due to the use of phosphates in detergents. In 1975, this proportion reached an average of 40 % in the Federal Republic of Germany. High phosphate levels in lakes and rivers constitute an ecological problem, leading to overfertilization, eutrophication, and excessive growth of algae, whose eventual death leads to oxygen deficiency, endangering aquatic organisms. For this reason, restrictions on the phosphate content of detergents and cleaning agents were introduced in many countries [66]. The search for a replacement lead to the development of zeolite NaA as a water-insoluble builder. It was important that the zeolite should have a small average particle size of ca. 3.5 µm and a narrow particle size distribution, to prevent incrustations in the textile fiber. More recently, the zeolite NaP has also been used as a builder component in detergents [134], [135].

The main function of zeolite NaA used as a detergent builder is to bind ions that cause hardness [93], [96], [136–138]. The ion exchange capacity with respect to Ca^{2+} ions is ca. 160 mg CaO/g (dry basis) at 20 °C, which is comparable with that of STPP, and ca. 190 mg CaO/g (dry basis) at 90 °C, exceeding that of STPP [66]. However, the rate of reaction with Ca^{2+} ions is lower than that of the soluble builders. The corresponding relative rates are even lower in the case of Mg^{2+} ions on account of the ion-sieve effect (Fig. 9). This preference of zeolite NaA for Ca^{2+} ions is not a problem, as tap water contains considerably lower concentrations of Mg^{2+} ions than of Ca^{2+} ions.

Figure 9. Ion exchange by zeolite NaA as a function of time [137]
$[Ca^{2+}]$, $[Mg^{2+}] = 0\,5.36 \times 10^{-3}$ mol/L; NaA zeolite: 1 g/L; temperature: 25 °C; Q_t: amount of Ca^{2+}/Mg^{2+} exchanged after time t; Q_{70}: amount of Ca^{2+}/Mg^{2+} exchanged after 70 min

Especially at high temperatures, the comparatively low rate of ion exchange in washing liquor, an alkaline medium, causes calcium carbonate to be precipitated before Ca^{2+} ions are taken up by the zeolite. For this reason, substoichiometric amounts of water-soluble cobuilders are added to the zeolite. In phosphate-free formulations, these generally consist of polycarboxylates in combination with sodium carbonate, and alternatively nitrilotriacetic acid, phosphonates, and citric acid. The Ca^{2+} ions in the washing liquor are initially bound to the

cobuilder, which transports them to the surface of the zeolite crystals where they are exchanged with Na^+ ions. Thus, the cobuilder acts as a carrier, and the zeolite as a means of storing Ca^{2+} ions, without which the polycarboxylates would be precipitated as calcium salts [137]. Furthermore, the cobuilder adheres to crystallization seeds of insoluble calcium salts, thereby preventing their growth (threshold effect). In Europe, phosphatefree heavy duty detergents contain 20 – 35 % zeolite NaA, 3 – 8 % polycarboxylates, and 5 – 20 % sodium carbonate as builder system [139]. In soft water areas such as Japan, where washing is carried out at lower temperatures (15 – 30 °C) than in Europe (30 – 95 °C), a cobuilder is not required.

The use of zeolite NaA also has positive side effects. For example, the zeolite adsorbs heavy metal ions present in trace amounts (e.g., Cu^{2+}) which impair the bleaching effect of perborate and percarbonate. Also, laundry discoloration due to adsorption of dissolved dyes, and graying due to retention of soil particles are minimized by heterocoagulation.

Extensive investigations have been carried out into the behavior of zeolite NaA in public wastewater systems and on the effects of its use on waterborne organisms and plant growth [93], [140]. No indications of harmful effects were found. A more recent study has shown that zeolite NaA in water undergoing treatment in sewage works retains the Ca^{2+} and phosphate ions present, converting them into an insoluble, relatively stable calcium aluminum silicate phosphate, and can thereby contribute to phosphate immobilization [141].

7.2. Adsorption

Along with silica gels, alumina, activated carbons, carbon molecular sieves, and organic resins zeolites are important industrial adsorbents with a wide range of uses [142–144]. Their diversity is due to the fact that zeolites not only have a high adsorption capacity but also show great selectivity, enabling substances to be separated or purified. Three effects contribute to the selectivity of a zeolite, and these can be influenced by the synthesis methods used to tailor it to requirements:

1) Zeolites are characterized by regular pores with definite aperture sizes, so that substances whose molecules are of different sizes can be separated (molecular-sieve effect, see Section 3.1). This selectivity can be influenced by post-synthetic operations, as explained in Section 6.3.1 using the example of ion exchange with zeolite NaA. The effect on the adsorption of various molecules of increasing the apparent pore size by transformation from 4A type to 5A type zeolite by calcium exchange is shown in Figure 10. Conversely, the pores can be narrowed to give 3A type zeolite by exchange with potassium salts, by steam treatment [5], or by appropriate choice of binder in the shaping process (Section 6.3.4).
2) The molecular-sieve effect described under (1) is a limiting case of kinetic selectivity, i.e., selection according to differences in the rates of diffusion of molecules into the zeolite pores.
3) The adsorption equilibrium is determined by electrostatic forces including dipole and quadrupole interactions, and also by dispersion forces. In high-alumina zeolites of types A and X (NaX is often denoted as 13X [*63231-69-6*] in adsorption technology) in which the negative framework charge is balanced by the appropriate number of cations, electrostatic interactions predominate. This favors adsorption by these zeolites of substances with a large dipole moment (e.g., H_2O and NH_3) or quadrupole moment (e.g., N_2). The interaction becomes stronger as the ratio of charge to radius of the cation concerned increases. In contrast, adsorption on high-silica zeolites is due only to van der Waals forces. The bonding affinity of adsorptive molecules is approximately proportional to their polarizability and therefore to their molecular mass. This is the reason for the hydrophobic surface of zeolites of this type (see Section 3.2). The interactions are especially favorable in this case if there is close contact between the pore walls and the adsorbed molecule.

Zeolites are used in adsorption technology both in gas and liquid phases. Processes can be classified according to the method of regenerating the loaded adsorbent and the method of

making the contact between the fluid and the adsorbent [142], [143]. In practice, pressure swing [145], [146] and temperature swing adsorption (PSA and TSA methods) are preferred. More rarely, desorption is carried out with a purge gas or displacement auxiliary at constant temperature and pressure (purge swing).

Figure 10. Effect of calcium ion exchange on zeolite NaA [5]
N_2 adsorption: 2.0 kPa, −196 °C; *n*-heptane adsorption; 6.0 kPa, 25 °C; isobutane adsorption: 53.3 kPa, 25 °C

Processes can also be divided into purification processes in which an undesired low-concentration component of a mixture of substances is adsorbed, and separation processes in which the components of the mixture are present in comparable amounts. The adsorption of water from gases and liquids is in fact a purification process, but, in view of its great economic importance, is discussed separately.

Static and Dynamic Adsorption of Water. Dehydrated ("activated") zeolites of types A and X are widely used in industry as drying agents in closed or open systems, i.e., for the static or dynamic adsorption of water. Their use is favored if small amounts of water have to be removed from gases or liquids. The adsorption isotherms in Figure 11 show that, unlike silica gel, zeolite NaA is able, for example, to reduce the dew point temperature of the gas to extremely low values. However, as water is very strongly adsorbed and is therefore difficult to desorb, zeolites cannot be considered for coarse drying in regenerative processes.

In drying operations, measures must often be taken to prevent larger molecules from being adsorbed and possibly undergoing catalytic reactions. This can be achieved using 3A zeolite whose pore diameter has been reduced to ca. 0.30 nm, e.g., in the drying of alkenes.

Figure 11. Adsorption isotherms for H_2O at 25 °C on zeolite NaA and silica gel at low partial pressures

A similar situation exists for the removal of atmospheric moisture from the panes of insulating glass [147], an important example of static adsorption. Here, the coadsorption of nitrogen and oxygen or insulating gases such as argon and SF_6 is undesired. Other examples of static adsorption of water by type A zeolites are the drying of coolant cycles and removal of moisture from solvent-free, noncellular polyurethane systems, in which reaction of the isocyanate component with water, forming CO_2 bubbles, must be avoided [148]. In this case, the zeolite powders remain in the cast resins, or sealing and coating compounds.

Dynamic water-adsorption processes include drying of air, natural gas, cracked gas, alkenes, and organic solvents using TSA and PSA methods with type A zeolites as the sorbents [5], [143], [145], [149], [150].

The large amount of heat liberated during the adsorption of water by high-aluminum zeolites could in future be used for zeolite-based heat storage and heat pumps. If, in another arrangement, a water reservoir were brought into contact with an activated low-silica zeolite via the gas phase, the evaporation, accelerated by the presence of the zeolite, would cause a large drop in temperature. This effect could be used for cooling [151].

Purification of Air and Gases. Zeolites of types A and X are well established in purifica-

Table 3. Commercial purification processes with synthetic zeolitic adsorbents (excluding drying)

Components removed	Crude gas	Zeolites	Refs.
CO_2	natural gas, air	4A, 5A, X	[144]
H_2S, organic sulfur compounds	natural gas, hydrogen	5A	[142]
SO_x, NO_x	waste air from H_2SO_4/HNO_3 plants	not published	[154]
Solvents, odoriferous substances	industrial waste air	dealuminated Y zeolites, silicalite-1	[152], [155]
Dioxins	waste air from incinerations	dealuminated Y zeolites	[156]
Hg	natural gas, cracked gas, hydrogen, naphtha	modified Y zeolites	[157]
	waste gas from incinerators		[153]

tion processes (Table 3). They are used to remove carbon dioxide from gas streams [144], and also to remove H_2S and organic sulfur compounds, mainly from natural gas. Problems can arise in H_2S adsorption if CO_2 is also present, as this reacts with H_2S on the zeolite to form COS [142]. As the activity of calcium-exchanged zeolite A is less than that of zeolite NaA in this reaction, 5A sieves are mainly used in this process.

The removal of solvents, dioxins, and elemental mercury from moist waste-air and exhaust-gas streams by hydrophobic, high-silica zeolites such as dealuminated Y zeolite is a relatively new field [152], [153]. Compared with other adsorbents, these materials have the advantage of high thermal capacity, nonflammability, low catalytic activity, and pronounced hydrophobic properties. Regeneration is possible even if the compounds adsorbed have high boiling points or can form polymers as the zeolite absorbent can be treated at high temperatures. Moreover, they are structurally stable in the presence of acidic components, such as SO_2 and HCl in incineration off-gases.

Separation of Substances. Zeolitic adsorbents of the 5A type are used in a number of important industrial processes for the separation of mixtures of substances (Table 4). They are alternatives to carbon molecular sieves and activated carbons for the recovery of hydrogen from reformer, refinery, and coke-oven gases in various PSA processes [146], [150], [158], [159]. Here, the separation effect is based on the fact that the gaseous components listed in Table 4 are adsorbed better than hydrogen.

The production of oxygen from air by vacuum pressure swing adsorption (VPSA) processes (→ Oxygen, Chap. 4.2.) represents a growing market for zeolites. Type 5A molecular sieves are mainly used, but the use of specially optimized lithium-containing X zeolites is increasing [146], [150], [160–162]. The separation of O_2 from N_2 is possible with these materials because the nitrogen molecule, which has a quadrupole moment, is more strongly bound than the oxygen molecule. The purity of the oxygen produced can exceed 95 %, but argon cannot be separated. VPSA processes are more economic than the cryogenic production of oxygen for flexible small to medium-sized plants [161].

The O_2/N_2 separation on 4A zeolite to produce nitrogen is based on the kinetically preferred adsorption of the smaller O_2 molecules. This process is hardly used on an industrial scale, but zeolites can be useful for oxygen removal in the production of ozone [146].

The separation of *n*-alkanes from iso-alkanes on 5A zeolites is of importance in the mineral oil industry. For example, PSA processes have been developed by UOP (Isosiv), Texaco (TSF), Leuna (Parex-Leuna), ELF (N-Iself), Exxon, and BP [142], [146]. In these processes, regeneration is sometimes performed by displacement media such as NH_3 or short chain *n*-alkanes. The Molex process of UOP is a liquid-phase process designed on the principle of simulated countercurrent chromatography (Sorbex technology) [163], [164]. All these processes are based on the fact that *n*-alkanes are adsorbed by 5A zeolites, while iso-alkanes are too bulky to enter the pore system (see Fig. 10) and therefore break through immediately.

Sorbex technology is also used for separating xylene isomers (→ Xylenes, Chap. 4.2.2.), alkenes from alkanes, and fructose from glucose (Parex, Olex, and Sarex processes of UOP) [163]. These separations, which take place on modified zeolites of the faujasite type, are due to the selectivity of cation – adsorpt interactions.

Table 4. Some important commercial separation processes with zeolitic adsorbents

Process	Mixture	Phase ∗	Technology	Zeolites	Refs.
H_2 production by removal of other gases (e.g., N_2, CH_4, CO, SO_2, H_2O, O_2, CH_4, C_2H_6)	reformer, refinery, and coke-oven gases	G	PSA	5A	[146], [150], [158], [159]
O_2 production	air	G	VPSA ∗∗	5A, modified X zeolites	[150], [160–162]
Ozone production	O_3/O_2	G	PSA	not published	[146]
Separation of *n*- from iso-alkanes	C_6-C_{10} distillate	G	VPSA ∗∗	5A	[142]
	$C_{10}-C_{18}$ kerosene	G	purge swing	5A	
	C_5-C_6, $C_{10}-C_{15}$, $C_{10}-C_{23}$ hydrocarbons	L	Sorbex (Molex)	5A	[163]
Separation of xylene isomers	C_8 aromatics	L	Sorbex (Parex)	Sr/BaX	[163]
Separation of alkenes from alkanes	C_8-C_{18} hydrocarbons	L	Sorbex (Olex)	Ca/SrX	[163]
Fructose/glucose	molasses, hydrolyzed starch	L	Sorbex (Sarex)	CaY	[163]

∗ G = gas phase, L = liquid phase.
∗∗ Vacuum pressure-swing adsorption.

As well as the industrial-scale processes mentioned, there is a growing list of potential separation processes based on zeolitic adsorbents, some of which are at the pilot plant stage.

7.3. Catalysis

Apart from the very alumina rich types such as A and X, which are unstable in acidic media, zeolites can be transformed into the hydrogen form [47]. In this form, they are solid acids which can show both Brønsted and Lewis acidity [165–168]. Brønsted acid sites are protons attached to framework oxygen atoms.

The number and strength of these sites depends on the SiO_2/Al_2O_3 ratio in the framework. Decreasing framework aluminum content is associated with a decrease in the number of acidic OH groups, but generally the strength of the remaining sites initially increases [168], [169]. Structurally related zeolite-like materials in which aluminum is isomorphously replaced by gallium or boron have weaker Brønsted acidity.

Methods used industrially to produce Brønsted centers include:

1) Careful ion exchange of intermediate-silica and high-silica zeolites (e.g., mordenite) with mineral acids (Eq. 6)
2) Removal of ammonia from the ammonium form at ca. 400 °C (Eq. 7) or the decomposition of tetraalkylammonium cations
3) Ion exchange with polyvalent cations, usually of rare earth (RE) metals, followed by a dehydration (Eq. 8)
4) Reduction of noble metal cations with hydrogen (Eq. 9)

$$Na^+[O{-}Z] + H^+ \rightarrow [{}^+H{}^-O{-}Z] + Na^+ \quad (6)$$

$$NH_4^+[{}^-O{-}Z] \rightarrow [{}^+H{}^-O{-}Z] + NH_3 \quad (7)$$

$$[RE(H_2O)_n]^{3+}[({}^-O{-})_3Z] \rightarrow [RE(OH)_2]^+[{}^-O{-}Z({-}O{}^-H^+)_2] + (n\text{-}2)\,H_2O \quad (8)$$

$$Pt^{2+}[({}^-O{-})_2Z] + H_2 \rightarrow Pt + [({}^+H{}^-O{-})_2Z] \quad (9)$$

$[({}^-O{-})_nZ]$ = zeolite framework

Calcination of the hydrogen form above ca. 400 °C causes decomposition of the acidic hydroxyl groups with liberation of water. This dehydroxylation leads to formation of Lewis acid sites. As dehydroxylation takes place at similar temperatures to those used in deammoniation (Eq. 7), both types of acidic sites may be formed at the same time. The question

whether these consist of three-coordinate Al or Si sites within the framework structure or of AlO^+ species outside the framework structure continues to be the subject of debate [168].

Base catalysis by modified zeolites has not yet been used in industry. Suitable zeolites are ion exchanged with rubidium and cesium ions or contain sodium clusters or cesium oxide as active species in their pores [170]. Bifunctional catalysts in which the acidity of the zeolites is combined with the hydrogen-transferring function of noble metals are important in large-scale industrial processes such as hydrocracking or C_5/C_6 alkane hydroisomerization (see below).

A unique feature of the use of zeolites as catalysts is that the reactions can be shape-selective [166], [171], [172]. Shape selectivity in catalysis is closely related to the molecular-sieve effect in adsorption. Thus, it can occur if the pores of the catalyst have similar dimensions to those of the molecules or transition states taking part in the reaction:

1) In reactant shape selectivity, only reactants that can penetrate into the pore system by virtue of their slender shape and which can thus diffuse to the catalytic sites of the interior surfaces take part in the reaction
2) If the more bulky of two possible products is not formed, this is known as product shape selectivity
3) Restricted transition state shape selectivity occurs if the reaction pathway in the zeolite is directed by spatial requirements of the possible transition states

In (1) and (2), the selectivity is ultimately a result of diffusion limitation.

Shape selectivity has so far mainly been observed in reactions in which the catalyst is ZSM-5. However, the phenomenon is not limited to the use of this material, as shown by shape-selective reactions on erionite, ferrierite, mordenite, and other zeolites and zeolite-like materials.

Zeolite catalysts are used in four fields of technology:

Oil Refining. Zeolite-containing catalysts play a central role in several oil-refining processes (Table 5) [173], [174]. The most important is fluid catalytic cracking (FCC), which converts vacuum distillates and residues into gaseous alkenes, gasolines, and diesel fuel. Y type zeolites have been used as active components in FCC catalysts since 1964 [46], [86], [175]. These materials constitute 5 – 40 % of the catalyst, which is spray granulated to give a mean particle size of 60 µm.

Table 5. Zeolite catalysts in oil refining

Oil fraction	Zeolite-catalyzed process	Zeolites
Naphtha	C_5/C_6 alkane isomerization	Pt/H-mordenite, H-ZSM-5
	reforming of C_6/C_7 alkanes	Pt/K-L, Pt/BaK-L
	M-forming	H-ZSM-5
Gas oil, lubricating oil	dewaxing/hydrodewaxing	H-ZSM-5, Pt/H-mordenite
	hydrogenation of aromatics/hydrodecyclization	noble metal – zeolite
Vacuum distillates, residues	FCC	RE-HY, USY, H-ZSM-5
	hydrocracking	Pd-, Pt-, Ni/Mo-, Ni/W-USY
	residue hydroprocessing	specially modified USY zeolites

The zeolite catalysts have higher activity and give higher gasoline yields and less coke formation than the amorphous alumina – silica and high-alumina catalysts formerly used. Today, mainly USY zeolites (see Section 6.3.2) are chosen for FCC catalysts. The extensive use of USY zeolites has reduced the consumption of RE-HY zeolites [*83984-84-3*] in this application. Hybrids of the two types are also used. The trend towards the use of USY zeolites, which began in the early 1980s, was a result of the prohibition of tetraalkyllead compounds as antiknock agents, necessitating an increase in the octane number of gasoline. The disadvantage of RE-HY zeolites is their high activity with respect to hydrogen transfer between alkenes and naphthenes, which leads to the formation of aromatics and alkanes. The latter lower the research octane number (RON) and motor octane number (MON) of the gasoline. The use of the less active USY types avoids this effect, which has been explained in terms of the greater distance between the active sites. Moreover, the USY types have higher hydrothermal stability and give a further reduction in coke formation and an increased gasoline yield.

There has been much discussion of the use of ZSM-5 as an additional catalyst, mainly in combination with RE-HY catalysts. ZSM-5 is

generally used in the form of a separate spray-granulated material with a binder content of ca. 75 %. The proportion of this zeolite in the total catalyst formulation is 0.5 – 3.0 %. The original aim was "octane boosting" by shape-selective cracking of unbranched hydrocarbons. Addition of ZSM-5 led to an increase in RON but does not always affect MON. However, another interesting effect is the increase in the proportion of C_3/C_4 alkenes, mainly propene, in the product spectrum. These alkenes can be used, for example, in the alkylation of isobutane, and can thus contribute to the increase in the octane number of the gasoline pool. However, the use of ZSM-5 does cause a slight reduction in the gasoline yield on cracking. Besides ZSM-5, other zeolites, such as beta, have been tested for possible use in the FCC process [46].

Residues from the distillation of crude oil contain high molecular mass carbon compounds and are contaminated with nickel, vanadium, sulfur, and nitrogen compounds. When these residues are cracked – a process that will increase in importance – basically the same zeolites are used as those for the catalytic cracking of gas oils [86], [176]. The main differences are in the catalyst matrix, which must have large pores and be catalytically active to precrack large molecules. The matrix must also contain additives to bond with the metals and chemically reduce SO_x, and promoters of CO oxidation.

In the hydrocracking process, an alternative to catalytic cracking, low-grade, high-boiling gas oils are converted into fuels, mainly kerosene and diesel. In this process, which is flexible with respect to the product spectrum, the majority of the catalysts used today are bifunctional, consisting of USY zeolites doped with palladium, platinum (ca. 0.5 %), or combinations of base metals such as nickel – molybdenum and nickel – tungsten [177]. The zeolite content of the catalysts is 5 – 80 %. To protect the hydrogenation components, conventional HDS/HDN (hydrodesulfurization/hydrodenitrogenation) catalysts for the removal of organic sulfur and nitrogen compounds are used prior to the hydrocracking catalysts. Specially modified Y zeolites, e.g., Fe-USY impregnated with Co/Mo, seem to be particularly suitable for the hydrocracking of residues [178].

To supply the current demand for fuels low in aromatics, new processes in which straight-run middle distillates are subjected to hydrogenation have been considered. Noble metal – zeolite catalysts that are stable towards sulfur and nitrogen compounds are used to hydrogenate or hydrodecyclize the aromatics [179].

Catalytic dewaxing is a technology for shape-selective cracking of *n*-alkanes in gas and lubricating oils to reduce the pour point of waxlike raw materials to temperatures below the usual limit of −5 °C. Catalysts for dewaxing under hydrogenating conditions include H-ZSM-5 and Pt/H-mordenite [166], [180].

Another important process in oil refining is the isomerization of C_5/C_6 *n*-alkanes with Pt/H-mordenite or H-ZSM-5. Shell has combined this with the adsorptive separation of *n*- and iso-alkanes (UOP Isosiv process) to give the TIP process (total isomerization process) [173].

The zeolites Pt/K-L and Pt/BaK-L may be used in the future for dehydrocyclization, especially of C_6/C_7 alkanes, as conventional reforming catalysts (e.g., Pt/Cl – Al_2O_3) show poor selectivity in this range [173], [181]. Problems still arise from sensitivity of the new catalysts towards poisoning by sulfur. M-forming is operated as a post-reforming process with H-ZSM-5 as catalyst. This consists of shape-selective cracking of *n*-alkanes with simultaneous alkylation of benzene and toluene by the short-chain alkenes produced [166], [182].

Conversion of Gases. Both methanol from synthesis gas and LPG (liquefied petroleum gas) are raw materials for mineral oils and petrochemical products. Shape-selective reactions, catalyzed mainly by the zeolite ZSM-5, make these conversions possible.

The MTG (methanol to gasoline) process developed by Mobil [183], [184] and used in New Zealand to produce gasoline from methanol aroused much interest in the past. Investigations into the mechanism have shown that the methanol is first converted by the catalyst H-ZSM-5 into the intermediate dimethyl ether by splitting off water, and then into short-chain alkenes. These form oligomers which undergo conversion into alkanes/cycloalkanes and aromatics by hydrogen transfer and cyclization. However, more recently, processes to obtain gasoline di-

rectly from synthesis gas with the aid of zeolite catalysts are being developed.

In the MTO (methanol to olefins) process, which is closely related chemically to the MTG process, the object is to obtain C_2-C_4 alkenes from methanol. Possible catalysts for this process include ZSM-5, narrow-pore zeolites of the erionite or chabazite type, and structurally modified silicoaluminophosphates (SAPO-17, SAPO-34, and SAPO-44) [185]. The short-chain alkenes obtained can be converted into middle distillates in zeolite-catalyzed processes such as MOGD (Mobil olefin to gasoline and distillates) or SPGK (Shell poly gasoline and kero) [166], [173].

The CYCLAR process, recently developed jointly by UOP and BP, uses a Ga-ZSM-5 catalyst to synthesize aromatics from LPG (C_3/C_4 alkanes), which is available in abundance [186], [187].

Petrochemistry and Synthesis of Organic Intermediates. The prospect of producing petrochemicals and organic intermediates in shapeselective catalytic processes has led to intensive research [188–190]. This work was to some extent also motivated by the fact that some large-scale processes are increasingly under pressure for environmental reasons, e.g., processes using acid catalysts such as H_2SO_4, HF, H_3PO_4 on silica, and $AlCl_3$. Unlike these acids, zeolite catalysts are noncorrosive.

Typical zeolite-catalyzed reactions which have led to industrial processes include the alkylation of aromatics with alkenes, the disproportionation of alkyl- and chlorobenzenes, the isomerization, oligomerization, and hydration of alkenes, and the formation of amines from alcohols and ammonia. Relatively new reactions include oxidations using hydrogen peroxide as the oxidizing agent and the molecular sieve titanium silicalite-1 as the catalyst, e.g., the hydroxylation of aromatics, the ammoxidation of ketones, and the epoxidation of alkenes [24], [191].

A selection of processes which have been operated on an industrial scale are listed in Table 6 [166], [192]. Of these, the production of ethylbenzene by the reaction of ethene with benzene (Mobil – Badger process) and the isomerization of xylenes are the most important processes [166].

Environmental Protection. Advances have been made in the use of zeolitic catalysts for selective catalytic reduction of NO_x to nitrogen in the exhaust gases of lean-burn and diesel engines [201–204]. Metal-modified zeolites, especially Cu-ZSM-5 materials, have been intensively investigated. Suitable reducing agents include hydrocarbons, oxygen-containing, water-miscible organic compounds, and CO and H_2. However, the durability of the new catalyst under working conditions is still insufficient for broad application. Therefore, for the moment only stationary systems and mobile systems with diesel engines, where the heat and water-vapor stress is comparatively low, will be equipped with these catalysts [204]. Special zeolites have also been used for the reduction of NO_x with ammonia in commercial applications [205].

7.4. Other Uses

Zeolites can act as carriers or reservoirs for reactive substances. For example, zeolites containing silver, copper, or zinc are used commercially as antibacterial powders applied in man-made fibers for textiles for domestic or personal use [206], [207].

8. Economic Aspects of Synthetic Zeolites

Since synthetic zeolites have become available in commercial quantities, world consumption of these materials has greatly increased. Starting from a few hundred tonnes in the late 1950s, this became 60×10^3 t/a in 1975, 460×10^3 t/a in 1987 [91], and ca. 1.2×10^6 t/a in 1994. An overview of the important producers of zeolites for various application fields is given in Table 7.

Although the main use of zeolites was initially adsorption, detergent builders now represent the largest application quantitatively, 1 050 000 t/a or almost 90 % of zeolites produced in 1994 having been used for this purpose. Of this, ca. 950 000 t/a was zeolite NaA, and ca. 100 000 t/a NaP, a material which has only more recently been used in detergent formulations. In Japan and Western Europe, zeolites have increasingly replaced phosphates as

Table 6. Zeolite catalysts in petrochemical processes and processes for the production of organic intermediates

Process	Zeolites	Process developer	Refs.
Production of ethylbenzene from benzene and ethylene	H-ZSM-5	Mobil-Badger	[166]
Production of cumene from benzene and propene (liquid phase)	HY	Chemical Research & Licensing Co.	[193]
Production of *p*-ethyltoluene from toluene and ethylene	Modified ZSM-5	Mobil	[166]
Isomerization of xylene	Pt/H-ZSM-5 Pt/H-Mordenite	Mobil and others	[166]
Disproportionation of toluene to produce xylene	H-Mordenite ZSM-5	Mobil UOP/Toray	[166]
Production of *m*-chlorotoluene, *m*-di-chlorobenzene and 2,6-dichlorotoluene by isomerization processes	H-ZSM-5 H-Mordenite	Toray	[194]
Amination of methanol by ammonia to give dimethylamine as the principal product	Na/H-Mordenite	Nitto	[195], [196]
Hydration of cyclohexene to cyclohexanol	H-ZSM-5	Asahi	[196], [197]
Production of pyridine from acetaldehyde, formaldehyde, and ammonia	H-ZSM-5	Nepera	[198]
High-purity isobutene from MTBE	B-ZSM-5	Snamprogetti	[199]
Cyclohexanone oxime by ammoximation of cyclohexanone	Titanium silicalite-1	Enichem	[24], [191], [200]
Hydroxylation of phenol to hydroquinone/catechol	Titanium silicalite-1	Enichem	[24], [191]

detergent builders since the late 1970s. In the United States, this development was interrupted in 1983, but since 1987 detergents with zeolite-containing formulations have been increasingly used there also. In 1994, ca. 55 % of all detergent zeolites were consumed in Western Europe, 30 % in the United States, and 15 % in the Far East (mainly Japan, Taiwan, and Korea).

Compared with the enormous consumption of detergent zeolites, the use of zeolites for catalytic purposes seems small, the world total for 1994 being 115 000 t/a. However, when applying monetary criteria, it must be remembered that the value addition achieved by the use of catalysts greatly exceeds the cost of the catalysts themselves [192]. Of the zeolites used in catalysts, type Y zeolites occupy a dominant position (ca. 105 000 t/a), and of this, 100 000 t/a is a constituent of FCC catalysts alone. This figure is based on an average content of 25 % Y zeolite in the catalyst. Approximately 5000 t/a is used in catalysts for hydrocracking and other special processes. The consumption of ZSM-5 zeolites for the purposes mentioned in Section 7.3 is ca. 3000 t/a, and of synthetic mordenite 600 t/a. Other zeolites are quantitatively of minor significance.

The zeolites used in adsorption are mainly types A and X. The total zeolite consumption for the diverse individual uses (see Section 7.2) was estimated to be ca. 50 000 t/a in 1994. Over half the catalysts and adsorbents that contain zeolites are produced and used in the United States. Western Europe and Eastern Asia follow some way behind.

Table 7. Synthetic-zeolite producers

Application	Zeolites	Producers
Detergent builders	NaA	Degussa AG (DE), Enimont (IT), Ethyl Corporation (US), Henkel KGaA (DE), Mizusawa Industrial Chemicals (JP), The PQ Corporation (US), Soprolit SA (BE), Zeochem SA (BE)
	NaP	Crosfield Chemicals (GB)
Catalysis	Y zeolites	Akzo Chemicals BV (NL), Catalysts & Chemical Ind. Corp. (JP), Engelhard Corporation (US), W.R. Grace & Co. (US), The PQ Corporation/Zeolyst Enterprises (US), UOP (US)
	ZSM-5, mordenite, and other specialty zeolites	ALSI-Penta Zeolithe GmbH (DE), CU Chemie Uetikon AG (CH), Degussa AG (DE), Eka Nobel AB (SE), Engelhard Corporation (US), Mobil Corporation (US), Südchemie (DE), Tosoh Corporation (JP), UOP (US)
Adsorption	A, X, specialty zeolites	Bayer AG (DE), Ceca SA (FR), Degussa AG (DE), W.R. Grace & Co. (US), CU Chemie Uetikon AG (CH), UOP (US), Tosoh Corporation (JP), Zeochem Company (US)

9. Toxicology

Epidemiological [208] and experimental investigations [209], [210] have shown that natural erionite, as found in Cappadocia (Turkey), can cause formation of mesotheliomas and bronchial carcinomas. The oncogenic activity of these minerals is explained in a similar way to that of asbestos, which has a fibrous crystal morphology. This crystal form is extremely rare in zeolites.

Natural erionite is so far the only example of a zeolite with toxic effects. A review can be found in [211]. Zeolite NaA, which is used as a detergent builder, was found to have negligible acute, subacute, chronic, or inhalative toxicity in comprehensive tests [66], [93], [212]. Furthermore, regular medical checkups of workers exposed to zeolite NaA for a period of years in production areas gave no indication whatever of fibrogenic or silicogenic effects [66]. In Germany, the MAK is 6 mg/m^3, i.e., the general dust threshold [93], [213].

1. Introduction

KARL ZIEGLER (1898 to 1973) was a Professor at the Universities of Heidelberg, Halle, and Aachen. From 1943 to 1969 he directed the Max Planck Institut für Kohlenforschung in Mülheim/Ruhr, Germany, where he led many research projects in the fields of organometallic chemistry and metal-catalyzed synthesis. His work was crowned by the award of the Nobel Prize for Chemistry, which he received jointly with GIULIO NATTA in 1963.

The research of ZIEGLER led to many industrial processes, most of which have already been described under other keywords. This article gives a brief overview of these processes, emphasizing the features they have in common. They include the Ziegler direct process for the production of aluminum triorganyls (Chap. 2), the industrial synthesis of Ziegler olefins (Chap. 3) and Ziegler alcohols (Chap. 4), and the versatile uses of Ziegler catalysts in the production of oligomers or polymers (Chap. 5).

2. Ziegler Direct Process

The Ziegler direct process is an important method of synthesizing aluminum trialkyls AlR_3 and dialkylaluminum hydrides R_2AlH (→ Aluminum Compounds, Organic, Chap. 1.). It is a loop process in which two reactions, known as hydrogenation and hydroalumination, proceed in parallel. In the hydrogenation step, aluminum reacts with hydrogen in the presence of AlR_3 to form dialkylaluminum hydrides. In the hydroalumination step, the aluminum hydride undergoes addition of an olefin. Taking triethylaluminum as an example, these reactions proceed as follows:

Hydrogenation:

$$Al + 1.5\,H_2 + 2\,AlEt_3 \xrightarrow[10-20\ MPa]{80-160\,^\circ C} 3\,Et_2AlH$$

Hydroalumination:

$$3\,Et_2AlH + 3\,CH_2{=}CH_2 \xrightarrow[0.1-1\ MPa]{80-110\,^\circ C} 3\,AlEt_3$$

Overall reaction:
$Al + 1.5\,H_2 + 3\,CH_2{=}CH_2 \longrightarrow AlEt_3$

The overall reaction is thus the formation of aluminum trialkyls from activated aluminum powder, hydrogen, and α-olefins.

Variation of the aluminum/olefin ratio enables the reaction to be directed towards the formation of trialkyls or towards dialkyl hydrides. The alkyl group can be varied. Apart from ethyl compounds, *n*-butyl and isobutyl compounds in particular are produced on an industrial scale. The industrial synthesis is continuous, and can be carried out in one or two stages. The ready availability of triethylaluminum afforded by the Ziegler direct process was an important precondition for the development of the stoichiometric and catalytic reactions of $AlEt_3$ described in the following Sections.

3. Ziegler Olefin Synthesis

In the early 1950s, ZIEGLER discovered the "growth reaction," in which the repeated insertion of ethylene into aluminum – ethyl bonds produces long-chain aluminum trialkyls, from which long-chain α-olefins were obtained in a subsequent displacement reaction [2]:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_505

This process has been realized on an industrial scale by Gulf Oil and Ethyl Corporation. The two processes are briefly discussed below. A detailed treatment can be found in → Hydrocarbons.

In the *Gulf Oil Process*, only catalytic quantities of triethylaluminum are used. The growth and displacement reactions take place in the same reactor. This process yields a relatively broad molecular mass distribution of linear $C_4 - C_{30}$ olefins. These products ("Gulftenes") are produced in a Gulf Oil plant at Cedar Bajou, Texas. Mitsubishi uses the same process in a plant at Mizushima, Japan.

In the *Ethyl process*, the Ziegler olefin synthesis is carried out in two successive steps. The first step, which uses catalytic quantities of triethylaluminum produces a broad distribution of olefins, as in the Gulf Oil Process. The short-chain olefins are fractionally distilled, and are then reacted in a second stage with stoichiometric amounts of aluminum trialkyls. Ethyl Corporation operates a plant based on this process in Pasadena, Texas.

4. Ziegler Alcohol Synthesis [3], [4]

In the production of alcohols by the Ziegler route, the aluminum trialkyls formed are oxidized by atmospheric oxygen to form aluminum trialkoxides, from which the long-chain alcohols are then obtained by hydrolysis (→ Fatty Alcohols, Chap. 2.4.1.):

Alfol Process. The first industrial realization of the Ziegler alcohol synthesis was by Conoco. In 1962, this company built an "Alfol" plant (now operated by Vista Chemical) at Lake Charles, United States. A similar plant was then constructed in 1964 by Condea-Chemie in Brunsbüttel, Germany. The products of particular interest are the alcohols of chain lengths C_{12}, C_{14}, and C_{16}, which can be sulfated to form fatty alcohol sulfates with good biodegradability. However, as in the Gulf Oil Process for Ziegler olefins, the Alfol Process also produces a mixture of products with a broad Poisson distribution. The coproduct aluminum oxides (→ Aluminum Oxide, Chap. 6.2.3.) have important industrial applications as starting materials for catalysts and ceramics.

Epal Process. The Epal process is a development of the Ethyl Corporation, and is based on the principle of the Ethyl olefin process (see Chap. 3). Growth reactions are followed by fractional distillation, enabling an alcohol mixture with a considerably narrower distribution of homologues to be obtained, e.g., in the desired $C_{12} - C_{16}$ range. The hydrolysis after the oxidation step is carried out with sulfuric acid, so that high-purity aluminum sulfate is obtained as a byproduct.

The Ethyl Corporation plant in Pasadena, Texas can produce alcohols as well as olefins. However, this flexibility requires a very complex plant, so that capital and operating costs are high.

5. Ziegler Catalysts

Catalyst Systems. The terms Ziegler catalysts and Ziegler – Natta catalysts are used to denote the general range of catalyst systems formed from the following building blocks:

1) An organometallic compound of a metal of groups 1, 2, or 13 (e.g., an aluminum trialkyl)
2) A compound of a transition metal from groups 4 – 8 (e.g., titanium tetrachloride)

These two components are mixed in an inert solvent and form polynuclear complexes. Even today, the structure and function of the various Ziegler catalysts are the subject of controversy in the literature. In a fundamental experiment with bis(cyclopentadienyl)titanium dichloride and diethylaluminum chloride it was

possible to isolate a binuclear complex with a vacant coordination site on the titanium:

It is assumed that unsaturated molecules such as ethylene are bound to this coordination site and then inserted into the titanium – ethyl bond. This insertion produces another vacant coordination site, and the process can begin again. If this chain mechanism is broken, oligomers are formed, but if the insertion reaction is repeated indefinitely, long-chain polymers are obtained.

Oligomerization with Ziegler Catalysts. The first oligomerization with a Ziegler catalyst system was discovered in 1952 by HOLZKAMP at the Max Planck Institut für Kohlenforschung [5], [6]. A growth reaction with aluminum alkyls and ethylene (see Chap. 3) was carried out with addition of nickel salts. The Ni – Al catalyst system led to exclusive formation of ethylene dimers (i.e., butenes) instead of a broad distribution of α-olefins. This "nickel effect" marked the birth of the Ziegler catalysts.

Ziegler catalysts based on titanium, zirconium, chromium, tungsten, cobalt, and palladium compounds can also be used for the oligomerization of ethylene [7]. In most cases, butenes are the main products. Higher olefins can be obtained by suitable choice of catalyst and reaction conditions.

Both propene and butene can be oligomerized with Ziegler catalysts. In the Dimersol process of the Institut Français de Pétrole (IFP) [8–10], propene and butene are dimerized or codimerized. The products are used as octane enhancers in gasoline or in the production of plasticizers (→ Hydrocarbons).

1,3-Dienes such as butadiene can also be oligomerized with Ziegler catalysts. Ziegler catalysts based on nickel or titanium dimerize butadiene to vinylcyclohexene and 1,5-cyclooctadiene, or trimerize it, forming 1,5,9-cyclododecatriene. The course of this reaction can be controlled by the addition of ligands [5], [6].

Polymerizations with Ziegler Catalysts [11–16]. By far the most important application of Ziegler catalysts is in the synthesis of polyolefins. The first catalysts for the polymerization of ethylene were based on β-titanium trichloride, which was produced in situ from $TiCl_4$ and aluminum ethyl chlorides. Since 1969, $MgCl_2$-supported Ziegler catalysts, which possess considerably greater activity, have been used (→ Polyolefins, Chap. 1.3.2.2., → Polyolefins, Chap. 2.1.).

In March 1954, in the Politecnico di Milano, NATTA first used the Ziegler catalyst $TiCl_4/AlEt_3$ with propene. Surprisingly, it was found that this reaction is stereoselective, and that crystalline isotactic polypropylene is formed. The first polypropylene plant was commissioned as early as 1957 by Montecatini in Ferrara.

A further important development in Ziegler catalysts was the use of metallocenes activated by methylaluminoxane (MAO) [17–21]. The hypothesis that the catalytically active species is an ion pair consisting of a metallocene cation and a stabilized methylaluminoxane anion is currently under discussion. These catalyst systems were discovered in the 1970s by KAMINSKY and SINN at the University of Hamburg, and very soon extremely high activities (e.g., 40 000 kg polyethene per gram metal per hour) were being observed.

Ziegler catalysts based on metallocene/MAO led to a new breakthrough in the synthesis of polypropylene in 1985. The use of bridged bis(indenyl)zirconocenes, developed by BRINTZINGER at the University of Constance, enabled isotactic polypropylene to be produced with extremely high catalyst activities and stereoselectivities.

Work is in progress on many other developments worldwide, and many polymerization plants will be put into operation based on new catalyst systems in the coming years.

1. History [1], [2], [4], [6–8]

Before 1500 A.D. the Chinese and Indians knew of zinc as a metal in its own right, and although it is not known precisely when zinc was first produced, coins containing 99 % zinc were cast during the Ming Dynasty (1368 – 1644). In a book written in 1637, the Chinese describe zinc production by controlled smelting in stacked, hermetically sealed pots. In India, remains of zinc smelting operations found in Sawai Madhopur (Rajasthan) confirm that zinc was produced prior to the 1300s. Although the Romans, the Greeks, and the entire western world knew how to produce brass, which was used as early as 8000 B.C. to make jewelry, metallic zinc was unknown. At that time, brass was produced by smelting copper ores or metallic copper with the zinc ore smithsonite. This method lasted until the 1800s. Brass smelting works were developed in the Middle Ages where localized deposits of smithsonite occurred in various places, e.g., near Lüttich and Aachen, and in Carinthia.

The efforts of the alchemists to convert base metals into gold led them to become interested in smithsonite, the ore that gave copper a golden color.

The first written sources to mention the word "zinc" appeared in the 1500s. However, the derivation is not entirely clear. The most likely assumption is that it is connected with the German word *Zinke* (the tooth of a comb), itself derived from *Zacke* (jagged peak), from the jagged appearance of the ore or of deposits in the furnace. A second possibility is that the word is derived from the Persian word *seng* meaning stone. Georgius Agricola (1494 – 1555), in his important *De re metallica*, describes how a material found in large quantities in the eastern Alps was called "zinc" by the local people. He gave the name "conterfey" to the white substance that was deposited at the front of the smelting furnaces during the treatment of Rammelsberg ores. This often consisted of metallic zinc, although he did not recognize it as such.

The metallurgical properties of zinc were first unambiguously described in Europe when zinc arrived there from India and China after the establishment of trade relations with the Far East.

In 1595, Libavius investigated a sample of this East Indian zinc imported from Holland and named "calaem." However, he confused it with silver and did not realize that it was the same material as that known as "cadmia" which was scraped off the walls of the furnace when Rammelsberg ore was smelted in the Harz Mountains to obtain lead and silver.

In 1617, Löhneyss also described this process and clearly recognized this metal as "zinc" or the "conterfey" already described by Agri-

10.1002/14356007.a28_509

COLA, used to imitate gold. KUNKEL (1700) and STAHL (1718) considered that smithsonite added a metallic component to the copper during brass production. In 1721, HENKEL produced zinc from smithsonite in Upper Silesia using a process that he kept secret. In 1746, in Berlin, MARGGRAF produced zinc by distilling smithsonite in sealed vessels. He described his production principle in detail, thereby establishing the basic theory of zinc production. The first industrial production of zinc was carried out in England, where it was produced on a large scale as early as 1720, probably based on knowledge of operating methods used in East Asia. CHAMPION patented a process adapted from brass production to produce zinc by distillation and built the first zinc smelting works in Bristol in 1743, with a capacity of >200 t/a zinc. He also patented the process for producing zinc from sulfidic ores after preliminary roasting. The English zinc industry is concentrated in Bristol and Swansea even today.

The German zinc industry was founded by RUBERG. The first zinc smelting works, which used the horizontal retort process developed by him, was built in Wessola in Upper Silesia in 1798. The raw material initially used was zinc galmei, a byproduct of lead and silver production. Later, it became possible to produce zinc directly from smithsonite, an easily smelted ore. This was shortly followed by the use of zinc blende, which had first to be converted into the oxidic form by roasting. After this development, other smelting works were soon erected in Silesia near the deposits, in the areas around Lüttich, Belgium and Aachen, Germany and in the Rhineland and Ruhr regions.

In the United States, the rich ore deposits led to rapid growth in zinc production in 1840, so that, by 1907, Germany, which had for long been the world's leading producer of zinc, was left behind.

The ores were often highly intergrown, and ore processing by sorting and flotation methods was started in the early 1920s.

At this time, the electrolytic production of high-purity zinc from sulfuric acid solutions was developed by the Consolidated Mining and Smelting Co. in Trail (Canada) and by the Anaconda Copper Co. in Anaconda, Montana (United States).

An important development in zinc production was achieved in 1930 at the New Jersey Co. in Palmerton (United States). Replacing the individual horizontal retorts by a single vertical retort enabled continuous operation and also yielded relatively pure zinc (ca. 99.5 %).

Statistical data on world production of zinc have been available since 1871. At this time, total production was 121 000 t/a, of which 58 000 t/a was produced in Germany and 45 000 t/a in Belgium. Total production at the turn of the century was 472 000 t/a and in 1913, 10^6 t/a. The earliest use for zinc was to produce brass for the manufacture of jewelry, domestic utensils, and coins.

Zinc castings were first produced on an industrial scale in the 1800s by GEISS (1805 – 1875). Backed by the building contractor SCHINKEL, the zinc foundry established by GEISS soon became of major importance.

The good resistance of zinc towards atmospheric corrosion soon led to its use in sheet steel production. The possibility of rolling zinc at 100 – 150 °C was discovered as early as 1805, and the first rolling mill was built in Belgium in 1812 by DONY. More such mills were built in Silesia from 1821 onwards.

Hot-dip galvanizing, the oldest anticorrosion process, was introduced in 1836 in France. This became possible on an industrial scale only after the development of effective processes for cleaning iron and steel surfaces. At first, only small workpieces were zinc coated. Continuous hot-dip galvanizing of semifinished products and wire came later.

2. Properties [1], [2], [7–11]

Physical Properties. Some physical properties of zinc are listed below. (see below)

The remarkably low boiling point of 906 °C (STP) is important in pyrometallurgical zinc production processes. Zinc can be worked at temperatures as low as 120 °C, and its good deformability is the basis for some of its uses.

In the electrochemical series, zinc is more negative than iron. The use of zinc in sacrificial anodes is based on this fact. The important use of zinc to coat iron to protect it from corrosion is based on the formation of passivating protective coatings of basic zinc carbonate by reaction with the atmosphere.

Chemical Properties. Zinc has an oxidation state of 2 in all its compounds. It forms complexes with ammonia, amines, and cyanide and halide ions. Zinc dissolves in mineral acids, usually with evolution of hydrogen, but in nitric acid with evolution of NO_x. Zinc is used as a strong reducing agent in chemical processes, mainly in the form of powder or granules. Zinc is resistant to air because of the protective coating formed. It is also resistant to halogens, but is rapidly corroded by HCl gas. Because of its high surface area, zinc dust is much more reactive and can even be pyrophoric, e.g., reacting vigorously at elevated temperatures with the elements oxygen, chlorine, and sulfur.

Zinc chloride and sulfate are very soluble in water, while the oxide, carbonate, phosphate, silicate, and organic complexes are insoluble or sparingly soluble.

3. Starting Materials for Zinc Production [1], [2], [4], [12–15]

3.1. Zinc Minerals

With an average concentration in the earth's crust of 65 g/t (0.0065 %), zinc is the 24th element in order of abundance. It occurs only in the chemically combined state. Like copper and lead, zinc is a strongly chalcophilic element. It usually occurs as the sulfide, mostly deposited from hydrothermal solutions and simic and sialic magmas. Sedimentary deposits are of less importance. A series of deposits in carbonatic strata shows the characteristics of true marine sedimentary deposits. However, in these cases it can be assumed that the metal was introduced by hydrohermal transport from simic magmas. Zinc deposits, classified according to their origin, are listed here in order of their economic importance:

1) Simic vulcanogenic-sedimentary deposits that sometimes occur as massive ore bodies and sometimes as impregnations, e.g., Kidd Creek (Canada), Mt. Isa and Broken Hill (Australia), Anvil Mine (Canada), Bleiberg (Austria), Reocin (Spain), and Rammelsberg and Meggen (Germany). Ores from these deposits represent 60 % of total world reserves.
2) Simic-hydrothermal or marine sedimentary deposits, e.g., Kipishi (Zaire), Kabwe (Zambia), Tsumed (South-West Africa), and New Zinc Belt and Old and New Lead Belt (United States). Approximately 30 % of all ore is produced from these deposits.
3) Sialic lodes (impregnation and replacement deposits), e.g., Bad Grund (Germany); western U.S. states such as Idaho, Colorado, and Utah; and Tepca (Jugoslavia). Only 10 % of world ore production is from these deposits.

Cadmium, silver, lead, and copper are important byproducts of zinc ore extraction. Isomorphous components of zinc blende such as cadmium, gallium, germanium, indium, and thallium do not form deposits of their own. Some of these metals are recovered during zinc ore processing.

By far the most important zinc mineral today, and probably also the only primary ore, is zinc blende. The other minerals listed here are of only local importance. Native zinc is practically nonexistent.

Zinc blende, sphalerite, ZnS, theoretical composition 67.09 % Zn, 32.91 % S, is light yellow to black in color, usually black to brown depending on the iron content, crystallizes in the regular tetrahedral system, and has a Mohs hardness of 3 – 4 and a density of 3.9 – 4.1 g/cm^3.

The most important impurity is FeS, which is always present at concentrations between 0.3 and >20 %. The grades with the highest iron contents are marmatite and christophite. Sulfides of Pb, Cd, Mn, and Cu are often present. Zinc blende also often contains small amounts of As, Sn, Bi, Co, Hg, In, Tl, Ga, and Ge, and nearly always contains Ag and often Au.

Wurzite is the hexagonal modification of ZnS. It often shows a conchoidal or radiating crystalline structure and is therefore also known as conchoidal or radiating blende. Its density is 3.98 g/cm^3.

Smithsonite, zinc spar, or calamine, $ZnCO_3$, has the theoretical composition 52.14 % Zn, 35.10 % CO_2. Some of the ZnO can be replaced by FeO, MnO, CaO, or MgO, so that the ZnO content can be as low as 20 %. Other typical impurities include SiO_2, Fe_2O_3, and Al_2O_3.

The Mohs hardness is 5 and the density 4.30 – 4.45 g/cm^3. The color is yellowish or reddish to brown, rarely colorless. Smithsonite crystallizes in the trigonal scalenohedral form and is usually amorphous or in amorphous mixtures with other carbonates. Minerals with higher impurity contents include manganese zinc spar (up to 15 % $MnCO_3$), iron zinc spar (up to 53 % $FeCO_3$), copper zinc spar (up to 6 % $CuCO_3$), zinc lead spar (up to 1 % PbO), and cadmium zinc spar (up to 7 % $CdCO_3$).

Hemimorphite, $Zn_2SiO_4 \cdot H_2O$, has the theoretical composition 54.30 % Zn, 24.94 % SiO_2, and 7.4 % water of crystallization of which 50 % is evolved on heating to 500 °C, the remainder at much higher temperatures.

The color is yellow to brown, more rarely colorless, green, or blue. It forms rhombic pyramidal crystals, but usually occurs in rough, massive, botryoidal, or earthy forms. Its Mohs hardness is 4 – 5 and its density 3.4 – 3.5 g/cm^3. It is often a component of "calamine" ores.

Willemite, Zn_2SiO_4, has the theoretical composition 58.68 % Zn, 26.95 % SiO_2. Its color can be white, yellow to reddish, greenish, or rarely blue. It forms rhombohedral crystals, has a Mohs hardness of 5 – 6 and a density of 4.0 – 4.2 g/cm^3, and can contain FeO and MnO as impurities.

Franklinite, $(Zn, Fe, Mn)O \cdot (Fe_2, Mn_2)O_3$ has the theoretical composition 21 % ZnO, 59 % Fe_2O_3, 11 % FeO, and 8 % Mn_2O_3, and can contain SiO_2, Al_2O_3, and MgO as impurities. Its color is black, it is weakly magnetic, and it forms cubic crystals, with Mohs hardness 6.0 – 6.5, and density 5.0 – 5.1 g/cm^3.

Other zinc minerals of minor metallurgical importance include zinc bloom or hydrozincite, $ZnCO_3 \cdot n\,Zn(OH)_2$; red zinc ore or zincite, ZnO; and troostite or bainite, $(Zn, Mn)_2SiO_4$.

3.2. Zinc Reserves

The proven zinc mineral reserves worldwide are estimated at 185.3×10^6 t zinc. Potential reserves amount to 118.1×10^6 t. The undoubtedly considerable Chinese deposits are not included in this estimate, as no concrete information on these is available.

The proven and potential reserves are listed in Table 1. Canada, with 37.7×10^6 t (20.3 %), has the largest reserves of any country, over 90 % of which are in stratified vulcanogenic-sedimentary deposits. North and South America account for over 45.4 % of known deposits. Western Europe has 16.7 % of world zinc reserves, of which the most important are in Ireland, Sweden, and Yugoslavia (Kosovo). Australia accounts for over 9.5 % of world reserves, the largest deposits being in Mt. Isa (Queensland) and Broken Hill (New South Wales).

Table 1. The zinc reserves of the world [2], [3], [12], [13]

Country	Proven reserves		Potential reserves	
	10^6 t	%	10^6 t	%
Canada	37 560	20.3	6 620	5.6
United States	31 800	17.1	32 200	27.3
Mexico	3 600	1.9	1 000	0.8
Peru	7 150	3.8	1 500	1.3
Brazil	1 790	1.0	480	0.4
Rest of Latin America	2 360	1.3	2 820	2.4
Africa	5 930	3.2	9 580	8.1
Germany	1 850	1.0	1 500	1.3
Sweden	4 000	2.2	2 000	1.7
Finland	2 000	1.1	1 000	0.8
Ireland	8 820	4.8	350	0.3
Spain	5 060	2.7	1 200	1.0
Italy	2 200	1.2	1 100	0.9
Yugoslavia (Kosovo)	3 500	1.9	2 000	1.7
Rest of Western Europe	3 420	1.8	2 250	1.9
Australia	17 560	9.5	27 950	23.7
Iran	3 700	2.0	1 800	1.5
India	2 650	1.4	3 500	3.0
Japan	9 150	5.0	6 100	5.2
Rest of Asia	1 160	0.6	3 100	2.6
GUS and Eastern Europe	30 000	16.2	10 000	8.5
Total world reserves	185 260	100.0	118 050	100.0

The most important deposits in the GUS, accounting for 13.2 % of the total, are in the central and eastern Kazak, Uzbek, and Kirghiz. The reserves in Poland (Upper Silesia) are also important.

3.3. Secondary Raw Materials [16], [17]

Typical secondary zinc raw materials include:

1) Electric steel plant dusts containing 20 – 30 % zinc (low grade) or 30 – 40 % zinc (high grade)
2) Liquor residues from zinc electrolysis containing 25 – 30 % zinc
3) Lead shaft furnace slags containing 10 – 15 % zinc
4) Residues from thermal zinc production containing 8 – 12 % zinc

Thermal enrichment of such products in the Waelz kiln process gives a Waelz oxide containing 50 – 58 % zinc and 8 – 12 % lead. The lead content can be reduced by calcination. Other sources of secondary raw materials include zinc dross, which is produced in galvanizing plants and has a relatively high zinc content (50 – 85 %); zinc-containing sludges (10 – 65 % zinc), spent catalysts (50 – 60 % zinc), and dusts from the brass industry (60 – 75 % zinc).

The increasing problems in disposing of zinc-containing materials are resulting in the continual extension of the range of zinc-containing secondary raw materials.

4. Pretreatment of Raw Materials for the Production of Zinc Metal [1–4], [10], [18–23]

Pyrometallurgical and electrolytic zinc production require an oxidic raw material. Sulfidic concentrates must be prepared for metal extraction by roasting, which removes the sulfur as SO_2 and converts ZnS to ZnO, but does not remove gangue material.

Low-zinc oxidic ores that are not suitable for mechanical beneficiation (e.g., by flotation), slag flue dusts, and other secondary raw materials are subjected to a thermal concentration stage, which usually consists of either slag fuming or roasting in a Waelz kiln.

4.1. Roasting

Both electrolytic and pyrometallurgical zinc production require oxidic raw materials. Sulfidic raw materials must therefore be converted to the oxidic form (known as calcine) before leaching or reduction.

Whereas early accounts of zinc metallurgy listed a large number of roasting processes, fluidized-bed and sinter roasting have now almost completely replaced older processes such as multiple-hearth and flash roasting. An essential requirement of any roasting process is that it must be possible to recover and use the SO_2 from the waste gas.

The various zinc production processes require feed materials with fundamentally different physical properties. A fine-grained calcine is necessary for leaching with dilute sulfuric acid. Flotation concentrates meet this requirement if oxidized by roasting in a fluidized bed. On the other hand, thermal processes require a porous feed material in lump form, as provided by sinter roasting [18].

Fluidized-Bed Roasting. Given a processed concentrate of suitable chemical constitution and particle size, the fluidized-bed reactor allows a calcine suitable for the leaching process to be produced. The parameters to be optimized are bed height, gas velocity, residence time, and temperature. In the fluidized-bed reactor, the reaction conditions are easily controlled and stabilized. The theoretical relationships, as shown in the phase diagram Zn – Fe – S – O (Fig. 1), have been thoroughly investigated [19], [22], [23]. Fluidized-bed roasters generally operate at conditions in which ZnO and Fe_2O_3 are stable. Developments in electrolytic processing technology have enabled the presence of sulfates and ferrites in the calcine to be tolerated.

Fluidized-bed furnaces are often operated in two stages, in the first of which the roasted product contains 6 – 8 % S. This overflows while hot into a second fluidized bed and is roasted with an excess of air to a residual sulfur content of <1.5 % [3, p. 662].

Sinter Roasting. The first industrial application of sinter roasting was in the roasting of lead ore in sintering pans. The crucial development in

processing technology came from the sintering of iron ores, the results from which are transferable to the sinter roasting of sulfidic concentrates [21]. It is important that the temperature of the mixture should reach the sintering point. This is determined by the fuel content of the mixture (i.e., in single-stage sinter roasting, by the ratio of concentrate to roasted recycled material), the particle size distribution of the mixture, and the flow resistance (controllable by means of the particle size), which in turn determines the air pressure difference both in the induced-draft and pressure sintering processes. The moisture content of the mixture is an important factor here. It is important that all parameters affecting the process should be kept as constant as possible. Automatic control is not yet widely used.

Figure 1. Phase diagram of the system Zn – Fe – S – O [23] The conditions that exist in most fluidized-bed roasters are indicated by the hatched area

In contrast to fluidized-bed roasting, where maximum reaction temperatures are in the range 900 – 950 °C and no volatilization occurs, maximum temperatures in the sintering zone reach 1450 °C, so that the cadmium and lead are volatilized to a considerable extent. For this reason, it is necessary to limit the maximum temperature in the sintering zone.

In principle, the temperatures in the reaction zone during sinter roasting are sufficient to ensure homogeneous sintering not only of concentrates but also of added flue dusts, dross, sludge, and other zinc-containing materials. An important advantage of sinter roasting is thus that it enables these materials to be prepared for shaft furnace treatment (Section 5.2) continuously and by the shortest route. The important characteristic parameters for sinter roasting, fluidized-bed roasting, and roasting in a multiple hearth furnace are compared in Table 2 [3, p. 662].

Table 2. Characteristic values for sinter and fluidized bed roasting compared with multiple hearth roasting , p. 662[3]

	Multiple hearth roaster	Sintering belt	Fluidized-bed roaster
Roasting capacity, $t\,S\,m^{-2}\,d^{-1}$	0.08	0.7	7.5
Throughput, t/d	60	500	800
Grain size, mm	1.5	5	3

SO_2 in exhaust gas, %	4 – 5	10	10
Steam output, t/t ore	0.4		1.0
Floor area, $m^3\,t\,d$	7	10	3

4.2. Pyrometallurgical Concentration Processes

The aim of pyrometallurgical concentration processes is usually the removal of zinc from flue dusts, slags, and low-grade, zinc-containing raw materials or raw materials of complex composition.

The Waelz kiln process was originally used for the treatment of low-grade oxidic ores to obtain oxide suitable for smelting [24]. It is now mainly used as an enrichment process to treat secondary raw materials from zinc metallurgy, e.g., slags, flue dusts, and sludges.

In the Waelz kiln process, the zinc and lead from the raw materials appear in the oxide product, together with much of the sulfur, chlorine, and fluorine, both from the raw materials and from the carbonaceous reductant. The zinc metal is usually obtained from the oxide product by a thermal process. For this, the oxide can be compacted by sintering or forming it into briquettes. If oxide with a low lead content is required, it must be calcined, i.e., reheated to 1100 – 1350 °C without addition of reducing agents, to volatilize the Pb as PbO. The

Waelz kiln process is carried out in a slightly inclined, slowly rotating, lined Waelz or rotary kiln through which air is passed at a controlled rate so that the mixture of raw material and coke breeze does not fuse together. The residues are discharged in a sintered but not molten state. Air from the furnace atmosphere diffuses to a limited extent into the reaction mixture which is carried up the walls of the rotating furnace, and a strongly reducing CO/CO_2 atmosphere is formed. This causes reduction not only of ZnO but also of zinc ferrites and silicates, and reoxidation to ZnO occurs after discharge. The following reactions take place in the rotating furnace:
Reaction in the solid charge:

$$ZnO + C \rightarrow Zn(g) + CO$$

Reaction in the gas space:

$$Zn(g) + CO + O_2 \rightarrow ZnO + CO_2$$

The heat liberated is due only to the overall reaction, i.e., the combustion of C to form CO_2, as the reduction of ZnO to Zn is immediately reversed in the gas space above the charge. The zinc oxide leaving the furnace space is collected in bag filters. As the sulfur and halogens in the waste gases are bound to the zinc oxide, there are no environmental problems. The iron compounds in the charge are reduced to wuestite and to some extent to iron metal. In practical operation, the composition of the reaction mixture must be correctly formulated and an excess of coke breeze must be present to prevent the iron-containing components from fusing and forming incrustations in the furnace. The temperature regime of the process can be controlled by means of the filling height, residence time, and air flow rate in the upper part of the furnace. Overheating can cause incrustations to form and must be prevented [24–27].

Slag Fuming. In contrast to the Waelz kiln method, with which a range of raw materials can be treated, the slag fuming process is only used to remove zinc from molten slags from lead and copper smelting [28]. The zinc oxide so obtained can be used for zinc production. The molten slag is blown with reducing gases, so producing zinc vapor, which is burnt in the gas space above the molten slag by secondary air. The resulting high-grade oxide is cooled in a waste heat boiler in an EGR and collected [3, p. 65]. The composition of the reaction products from slag fuming in Port Pirie (Australia) is given in Table 3.

Table 3. Composition (in wt %) of reaction products from a slag fuming plant in Port Pirie, Australia

	Zn	Pb	CaO	FeO	SiO_2	F	Cl	S
Slag before Zn removal	18.3	2.6	14.7	25.6	21.0	0.1		1.7
Slag after Zn removal	2.6	0.03						
Oxide	66.0	12.5				0.25		0.2

Oxide Calcination. The oxides obtained from Waelz kilns or slag fuming plants can be compacted in preparation for further processing by sintering or briquetting, without pretreatment. However, for electrolytic processing, for pigment use, or for production of other zinc compounds, removal of harmful elements such as Pb, Cl, and F is required. This is carried out by calcination in rotary kilns at 1100 – 1150 °C. Not only are the harmful impurities removed, but the material is also densified [29], [30].

Figure 2. Annual outputs of the various zinc production processes expressed as a percentage of total annual output (idealized curves) [3, p. 664]

5. Production of Zinc Metal [1–5]

There are five industrial processes for the production of zinc: one electrolytic and four pyrometallurgical. Their relative importance during recent decades is illustrated in Figure 2 [3, p. 664]. Although the horizontal retort was the most important zinc production process at the turn of the century and still accounted for ca. 50 % of total production capacity in 1950, the process is no longer of practical importance. The question of whether the energy-intensive electrolytic zinc production process can retain or even extend its lead depends on the development of the energy supply situation.

5.1. Pyrometallurgical Zinc Production by the Retort Process

Zinc oxide, produced by roasting, is reduced by carbon according to the equation

$$ZnO + C \rightleftharpoons Zn + CO \quad \Delta H = 353\ kJ$$

The reaction is so strongly endothermic that 5.4 MJ of heat is required to produce 1 kg of zinc. The reaction starts at ca. 1100 °C and is complete at 1300 °C, and the zinc (*bp* 920 °C) is therefore produced as a vapor. Zinc production by the retort process hence involves not only reduction of the oxide but also condensation of the zinc from the vapor to the liquid state. Care must be taken to prevent reoxidation, and the zincvapor must not come into contact with the combustion gases. The reduction must therefore be carried out either in vessels with exterior heating (retorts) or by the electrothermal method. Horizontal, batch-operated retorts with circular or elliptical cross section can be used, or furnaces containing vertical, continuously operated retorts with a rectangular cross section. The quality of the furnace vessels is of great importance for the process, especially their stability at high temperature, resistance to large temperature fluctuations, good thermal conductivity, impermeability to reaction gases, and resistance towards chemical attack by the charge materials.

Reduction in Horizontal Retorts. Zinc has been produced in horizontal retorts since ca. 1800 in Belgium and Upper Silesia from smithsonite and later from roasted zinc blende. Retorts vary in their shape and arrangement in the furnace and in the fitting of receivers, in which the zinc vapor produced in the retort condenses as a liquid. Detachable devices made of sheet metal (so-called allongen) are fitted to the condensers to collect zinc escaping in the form of dust.

The retort furnaces are equipped with regenerators or recuperators which utilize the hot waste gases to preheat the combustion air and sometimes the fuel gas. The retorts used to be charged by hand, an extremely labor-intensive operation: one worker smelted ca. 0.5 t ore per shift. Moreover, the yield was poor, only 60 % of the zinc being obtained as molten castable metal, 10 % remaining unreacted in the ash produced, and the rest reporting to the dross and dust in equal amounts. Although efforts were made to mechanize the process, especially the charging and discharging of the retorts, the main problem, i.e., the poor efficiency (ca. 20 %), could not be solved. The horizontal retort is no longer an industrially important zinc production process.

Reduction in Vertical Retorts. The poor efficiency, batch operation, and above all labor intensity of zinc production in horizontal retorts provided the incentive to develop an improved process. The fact that the horizontal retort was inconsistent with the natural downward movement of the charge and upward movement of the zinc vapor suggested that a vertical arrangement would be better. Zinc reduction furnaces were therefore constructed with vertical retorts, but only after overcoming major difficulties. The system is known as the New Jersey process. The furnace, illustrated in Figure 3, consists of a retort 13.5 m high, 1.83 m long, and 0.3 m wide, constructed of silicon carbide. The retort is externally heated over a vertical length of 8 m (starting at 1.5 m from the lower end) to a temperature of 1250 – 1300 °C. Producer gas is fed from above into the heating chambers, and the exhaust gas phases out of the furnace at the bottom. The reaction air is fed through the sides of the furnace along its whole length. Above the heated part of the furnace is an unheated part 4 m in length which acts as a reflux condenser for the lead formed and is known as the lead collector. In the original design, the gas mixture passing out of the retort at 850 °C was cooled

to 500 °C by a plate cooler, which also condensed and collected the zinc. This was tapped off from time to time. The zinc dust formed was collected by means of a water spray. The process was much improved by replacing the plate cooler by a spray condenser. A graphite disc, partially immersed in the pool of molten metal and spinning at ca. 400 rpm, atomizes the metal so that the waste gases from the retort passes through a metal fog. The metal is collected at 500 °C in an exterior cooler. This prevents formation of dross, and the amount of zinc dust formed is reduced to 3 % of the zinc product.

The charge material, containing 60 – 70 % calcine and 30 – 40 % coal, is formed into briquettes, which are then coked in a coke oven. The coked briquettes are charged into the top of the retort. After extraction of the zinc from the briquettes, they are discharged from the bottom of the retort through a water lute. The zinc-containing gases discharged from the top of the retort are cooled to ca. 500 °C in a condenser, in which the molten zinc collects at the bottom. The tail gases produced, which contain ca. 85 % carbon monoxide, are scrubbed and recycled to the producer gas stream. Furnaces with vertical retorts are much more thermally efficient than those with horizontal retorts, and they have the further advantages of providing higher capacity, higher zinc purity, and longer working life of the retorts, and, above all, do not involve heavy manual labor or batch operation.

5.2. Zinc Production in the Shaft Furnace [31]

Prolonged and extensive development work in the 1950s, aimed at utilizing the improved thermal efficiency and higher reaction temperatures of the coke shaft furnace, led to the lead – zinc shaft furnace of the Imperial Smelting Corp. Thus, a process became available that could be used with raw materials of complex composition, such as mixed ores and secondary raw materials containing impurities that would cause severe problems in electrolytic zinc production.

In the shaft furnace, the heat for the reduction is provided by the oxidation of C to CO_2 and CO. Under the reaction conditions normally used in a shaft furnace, the zinc vapor formed would be reoxidized to ZnO by the CO_2 in the furnace gas. Intensive research on the equilibria enabled conditions to be found under which this reoxidation does not occur.

In normal shaft furnace operation, the best possible heat utilization is achieved by using countercurrent flow to heat the charge material. The furnaces are relatively tall, and furnace gas exit temperatures of ca. 200 °C are aimed for. In accordance with the Boudouard equilibrium, this results in higher CO_2 contents in the furnace gas. The zinc shaft furnace requires gas temperatures of 1000 °C. In order not to lower the furnace gas exit temperature by the addition of the cold charge material, the coke is heated to >800 °C and the calcine is added as hot sinter.

The shaft furnace obtains its heat of reaction from the combustion of coke in the reaction zone. This leads to large amounts of nitrogen in the furnace gas, lowering the partial pressure of the zinc. Therefore, the heat required is generated to a large extent outside the furnace. Thus, the combustion air is preheated to 700 – 950 °C, enabling the amount of furnace gas to be much reduced. The CO-rich furnace gas is cooled as it

passes from the furnace to the condenser. To prevent reoxidation of zinc to ZnO, a small amount of atmospheric oxygen can be added to avoid a temperature drop. This process step must be carefully controlled.

The zinc collects in a spray condenser. In contrast to the vertical retort process, lead is used as the condensing liquid instead of zinc. Dissolving zinc in lead greatly reduces its activity. As the solubility of zinc in lead is strongly temperature dependent, the zinc can be precipitated by cooling. In practice, a temperature of ca. 550 °C is maintained in the spray condenser. The metal flowing out of the condenser is cooled to 440 °C, causing the zinc to separate from the lead and float on the surface. It then flows over a weir and is collected. As the process does not take place under equilibrium conditions, the recovery of 1 t zinc does not require the theoretically calculated amount of lead (60 t), but ca. 400 t. The zinc is either cast as commercial grade ingots (98.5 % Zn) or refined to higher grades.

The first full-scale industrial furnace went into operation in Swansea in 1960. The cross-sectional area of the shaft was 17.2 m^2, and this remains the standard size even today.

On licensing its ISO process, Imperial Smelting required that licensees should compare their experiences of the process, and this has led to standardization of the major zinc-producing plants and to improvements in the plant performance. For example, the annual output of a furnace with a cross section of 17.2 m^2 has been increased from 35 000 t zinc and 17 000 t lead in 1963 to 80 000 t zinc and 40 000 t lead in 1990. At the same time the zinc yield was increased from 91.7 to 95.5 %, and the lead yield from 94 to 95 %. The Pb : Zn ratio in the charge material was increased from 0.49 to 0.6, further enhancing the main advantage of the process, i.e., its ability to treat ores of complex composition. In addition to Zn and Pb, many ores also contain Cu. Most of this is reduced to the metal and dissolved by the lead. Copper contents below 4 % give few problems, as the copper separates as dross on cooling the lead and can be removed in the form of a solid crust. Higher concentrations can give problems due to the limited solubility of copper in lead. Special techniques are then required. A schematic diagram of a lead – zinc shaft furnace is given in Figure 4.

5.3. Refining of Crude Zinc

Zinc produced hydrometallurgically (see Section 5.4) does not need to be refined. However, crude zinc produced by pyrometallurgy contains 0.7 – 3 % Pb, up to 0.2 % Fe, up to 0.3 % Cd, and sometimes small amounts of As, depending on the production method and the composition of the ore. The zinc used to produce pressure casting alloys should have a purity of 99.99 – 99.995 %, and galvanizing processes require a purity of 98.5 – 99.95 %, depending on the process used. Commercial grades of zinc cannot be produced simply by remelting and liquation or by treatment with fluxes. Simply cooling zinc melts until they approach the eutectics in the systems Zn – Pb or Zn – Fe does not produce the theoretical compositions 0.8 % Pb and 0.02 % Fe, respectively. The concentrations obtained in practice are 1.2 % Pb and 0.03 % Fe.

Hence, these processes are only suitable for producing zinc for the next stage of purification by distillation or for producing zinc dust. The refining of commercial zinc produced by a pyrometallurgical process (today usually the Imperial Smelting Shaft Furnace process) is carried out by distillation in high-temperature distillation columns constructed of ceramic-bonded SiC elements. The process was developed by the New Jersey Zinc Co., Palmerton (United States), and the first plant went into operation in 1932.

The distillation process makes use of the comparatively low boiling point of zinc (906 °C). However, as not only impurities with a high boiling point such as lead, copper, tin, and iron must be removed, but also cadmium, which boils at 762 °C, the refining process must be carried out in two stages. A plant based on the New Jersey process is illustrated in Figure 5. Molten crude zinc is fed into the top third of a distillation column, the lower part being heated to ca. 1100 °C. The upper part acts as a reflux cooler for the less volatile constituents, so that only Zn and Cd pass into the condenser. Because of the relatively small difference in boiling point between zinc and cadmium and the low cadmium content, a further very careful fractional distillation must be carried out. The column for this is heated to ca. 950 °C, and the Cd which distills off is collected as a dust with a high zinc content. Depending on the composition of the initial

materials and the quality of the process control, the zinc produced can have a purity of 99.996 % and the concentration of the undesired elements Pb, Cd, and Fe can be <0.001 %.

a) Melting furnace; b) Lead column; c) Condenser; d) Cadmium column; e) Cadmium canister; f) High purity zinc furnace; g) Washed inc furnace

The "washing" zinc produced in the lead column contains Pb, Fe, Cu, and sometimes also In and Tl. The washing zinc is liquated, giving hard zinc and very impure lead. The hard zinc is recycled to the process, but the lead can be treated separately. In practice, this very impure lead is often added to crude lead from a smelter before it is refined.

The working life of the distillation columns is 2 – 3 years, and the energy consumption for 1 t of purified zinc is 6.5 – 7.3 GJ.

5.4. Hydrometallurgical Zinc Production [1–5], [10], [13]

Zinc can be deposited electrolytically both from aqueous solutions and molten salts. However, only aqueous electrolytes (i.e., solutions of zinc sulfate in dilute sulfuric acid) have so far been used in industry. Other proposed processes such as the electrolytic production of zinc dust, amalgam electrolysis, and sulfate – chloride electrolysis have not attained industrial importance. Although a full-scale version of the electrolytic refining process, in which the impure zinc forms the anode, has been developed, it is not used, the

reasons being mainly economic. The electrolytic production (electrowinning) of zinc from solutions of zinc sulfate in sulfuric acid has undergone unparalleled growth in recent decades. Approximately 80 % of total world production comes from this process today, although a number of problems still need to be solved, principally in the preparation of pure electrolyte solutions.

Figure 6. Flow diagram of the electrolytic zinc production process [2, p. 602]

Like the thermal processes of zinc production, the industrial electrolysis of zinc uses oxidic starting materials. The most important natural raw material, zinc blende, therefore still needs to be roasted to be converted to oxide. To ensure rapid dissolution of the calcine, the roasting processes used should therefore conserve the fine grained structure of the concentrate obtained by flotation. Commercial zinc oxide can usually be used directly and need only be treated if it contains impurities that have a harmful effect on the electrolytic process. Roasted oxide must be ground to improve its solubility. Using typical starting materials, the electrolytic process of zinc production consists of the following stages (Fig. 6):

1) Roasting
2) Leaching
3) Liquor purification
4) Electrolysis
5) Melting and casting.

The main problem in leaching and liquor purification is zinc – iron separation. In earlier processes, leaching was carried out such that a large excess of acid was avoided. Thus, the calcine and acid (exhausted electrolyte) were added simultaneously to the leaching tanks, the amount of acid being exactly that required to dissolve the zinc oxide. High yields of zinc could only be obtained with concentrates containing ≤ 3 % Fe. Iron in higher concentrations was dissolved to some extent. The solid residues contained ca. 20 % Zn and 30 % Fe. However, as a result of the roasting process, part of the zinc in the calcine is in the form of zinc ferrite ($ZnFe_2O_4$), which can only be dissolved at higher acid concentrations (50 – 150 g H_2SO_4/L). Maximum yields of zinc and also of other valuable impurities such as copper and cadmium require the use of higher acid concentrations in the leaching process. Hence, almost complete dissolution of the iron content of the zinc blende cannot be avoided. As the iron interferes with the electrolytic process even at low concentrations, it must be precipitated from the zinc sulfate solution obtained.

Precipitation of Iron Hydroxide. Precipitation of iron as its hydroxide has now been largely superseded owing to the poor zinc yield obtained (85 – 88 %). The process is usually carried out in two stages.

The readily dissolved zinc oxide fraction is brought into solution by "neutral leaching" in a mixture of cell acid (150 – 200 g H_2SO_4/L) and the acidic solution (ca. 50 g H_2SO_4/L) produced during iron precipitation. At this stage of the process, it should be ensured that impurities such as

iron, arsenic, antimony, and germanium are retained in the solid residues. A solid – liquid separation is carried out, giving an impure neutral liquor which is fed to the purification stage and a zinc-rich residue which is fed to the second, acid leaching stage, for which hot (ca. 95 °C) cell acid is used. A further solid – liquid separation produces a solid residue containing up to 5 % zinc and any lead and silver present (which can be processed in a lead smelter) and a zinc solution containing ca. 80 g/L zinc together with the iron and other impurities, such as arsenic, antimony, germanium, nickel, and cobalt.

After oxidation of Fe(II) to Fe(III) in the solution obtained by "neutral leaching," the iron is precipitated as its hydroxide by adding further calcine. The precipitation starts at pH 2.6 and continues up to pH 5.0. This gives solutions with residual iron contents of 10 – 20 mg/L. Because precipitation of iron causes arsenic, germanium, and zinc to be adsorptively coprecipitated, and the calcine used for neutralization cannot be subjected to hot acid leaching, this process gives unsatisfactory zinc yields. Higher zinc yields are only possible if the leaching residues can be more readily filtered. Three methods of achieving this are available, i.e., precipitation of the iron as jarosite, goethite, or hematite.

Iron Removal by the Jarosite Process. In the jarosite process, an Fe(III) compound of the type $X[Fe_3(SO_4)_2(OH)_6]$, where X represents H_3O^+, Na^+, K^+, or NH_4^+, is precipitated by adding alkali metal or ammonium ions. These compounds correspond to the mineral jarosite. The process was independently developed between 1960 and 1965 in various zinc smelting plants arount the world. It makes use of the fact that jarosite precipitates have the following advantages over iron hydroxide:

1) They are almost insoluble in sulfuric acid
2) They have a high iron content, so that the amount of precipitate formed is low
3) They have good filtering properties

However, jarosite precipitates do not adsorb the harmful impurities as effectively, so that the purification effect of the process is inferior.

The additional cations needed for the precipitation are added to the liquor in the form of sulfates. In practice, ammonium sulfate, which forms an ammonium jarosite, is usually used.

Figure 7. Flow diagram of the jarosite process with preneutralization [3, p. 678]

A flow diagram of the process is given in Figure 7.

Precipitation of jarosite begins at pH <1 and is complete at pH 1.5. Jarosite formation and precipitation being a temperature-dependent process, two alternative industrial processes exist, the first operating at temperatures up to 180 °C and with relatively high acid concentrations (60 – 90 g H_2SO_4/L) giving a high reaction rate, and the second at ca. 95 °C and considerably lower acid concentrations (5 – 10 g/L). The lower temperature method is more widely used, mainly because of the lower equipment costs.

Jarosite theoretically contains 37 % iron and 13 % sulfur as sulfate. In practice, these values are not reached, as the calcine added for pH control is not completely dissolved and hence adds impurities to the solid residue. For this reason, additional leaching processes are carried out, giving zinc contents of 4 – 6 % in the residue. Zinc yields of 96 – 98 % can be achieved by the jarosite process. As the jarosite contains sulfate, it helps regulate the sulfate balance of the plant.

Figure 8. Flow diagram of the goethite process [3, p. 679]

Worldwide, the jarosite process has superseded the precipitation of iron hydroxide. However, problems are caused by the fact that the jarosite contains small amounts of soluble zinc and so must be deposited in special waste disposal sites. New processes aimed at further increasing the zinc yield have therefore been developed.

Iron Removal by the Goethite Process. As the flow diagram (Fig. 8) shows, the first stages of the goethite process are the same as in the jarosite process. The solution from the first hot leach is then treated with zinc concentrate. The zinc dissolves, reducing the iron to the divalent state, and elemental sulfur is precipitated, so that compounds other than goethite (e.g., jarosite) are not precipitated in the final precipitation process. The excess zinc concentrate and the elemental sulfur are recycled to the roasting process. Oxygen is added in a controlled manner, precipitating goethite, FeO(OH), at pH 2 – 3.5 and 70 – 90 °C.

The advantage of the goethite process is that the amount of residue that must be disposed of is considerably less than in the jarosite process. Whereas the zinc yield is comparable to the jarosite process, the yield of copper is lower (80 % instead of 90 %) and that of silver is higher (96 % instead of 90 %). As the goethite produced, which contains 40 – 45 % iron, always contains small amounts of basic sulfates, it cannot be used in blast furnaces.

Iron Removal by the Hematite Process. The hematite process (Fig. 9) was developed to enable iron-containing residues from zinc production to be disposed of at moderate cost and without ecological problems. It differs from the other processes in that the residues are subjected to reductive leaching in which the reducing agent is an excess of zinc concentrate. The iron is reduced with formation of elemental sulfur. The insoluble solids and the liquor are heated in autoclaves, causing the sulfur to melt and wet the excess of zinc blende, forming small pellets. These are cooled, classified, and fed to the roasting plant. A lead – silver residue which separates from the solution is sent to a lead smelting plant. The liquor is preneutralized with calcine, and the resulting precipitate is recycled to the hot reductive leaching stage. The copper is precipitated from the zinc – iron solution by addition of zinc (cementation), and the solution is then neutralized with calcium carbonate. This is followed by the most important stage of the process, pressure

treatment in an autoclave at 200 °C at an oxygen pressure of 10 – 15 bar. Under these conditions, iron is precipitated as Fe_2O_3 (hematite), which can be used in iron metallurgy. The zinc solution is recycled to the neutral leaching stage. The gypsum produced is dewatered and can then be used in the building materials industry. The yields of zinc and other valuable metals are comparable to those in the jarosite and goethite processes. As the iron can be produced in the form of a useful product, no landfill space is required. However, the costly and complex technology is restricting more widespread use of the process.

5.5. Treatment of Leaching Residues

Residues from calcine leaching are primarily subjected to pyrometallurgical treatment. In some plants of older design, the residues from the neutral leaching stage are treated in a Waelz kiln. This removes the lead, and the resulting sinter oxide is ground and recycled to the leaching process. In a development of the classical Waelz kiln process, vaporization is carried out in a Waelz kiln fitted with an external burner. A rotary flame-fired furnace of the Dörschel type can also be used in a batch process.

A combination of flotation with pyrometallurgical and hydrometallurgical processes (sulfating roasting followed by leaching) enables the valuable metals to be recovered from the leaching residues.

5.6. Liquor Purification

Impurities still present in the unpurified neutral liquors from the iron precipitation stage can lead to:

1) Lower current efficiency
2) The presence of impurities in the cathodically deposited zinc
3) Adverse effects on the anode and the cathode

If the critical impurity concentrations are exceeded and several impurities are present simultaneously, the electrolytic process may no longer be possible. The concentration limits of the harmful impurities cannot be precisely specified, but the following guidelines can be used (mg/L):

Figure 9. Flow diagram of the hematite process [3, p. 680]

As	0.01 – 1.
Sb	0.05 – 0.1
Ge	0.002 – 0.05
Ni	0.05 – 3.0
Co	0.1 – 1.0
Fe	20 – 30.

In the formerly used iron hydroxide precipitation process, the adsorptive effect of the hydroxide precipitate caused most of the arsenic, antimony, and germanium to be removed along with the iron, so reducing their concentrations below the acceptable limits.

However, when the residues from the neutral leaching are subjected to hot acid leaching (mainly in the interest of higher zinc yields), the neutral liquors contain much higher levels of impurities. As these are not removed either in the iron precipitation or the leaching stage, careful purification of the liquor is necessary. In principle, there are the following possibilities:

1) Chemical precipitation
2) Electrochemical deposition
3) Ion exchange (solvent extraction)
4) Cementation with zinc

For high quality requirements, a combination of methods can be used. Chemical precipitation is mainly used for nickel and cobalt. For example, nickel can be precipitated by dimethylglyoxime and cobalt by α-nitroso-β-naphthol. However, as these reagents are expensive, their use can only be considered in exceptional cases for liquors with very low levels of impurities.

Processes involving the use of fluidized-bed electrolysis to remove impurities more noble than zinc and the use of solid and liquid ion exchangers are still at the development stage.

In most zinc electrolysis plants, the liquor is purified by cementation of harmful elements on zinc dust in a continuous, multistage process. An inert coating can form on the zinc particles or they may be chemically dissolved. Therefore, not all the zinc dust added can take part in the cementation process and a large excess of zinc dust (5 – 10 fold) is necessary to ensure effective purification.

A typical process used in many plants is the hot – cold liquor purification process (Fig. 10), which has two successive precipitation stages.

Figure 10. Hot-cold liquor purification [2, p. 607]

In the first stage, copper, nickel, and cobalt are precipitated by adding zinc dust in the presence of an added activator, usually As_2O_3. In the second stage, copper sulfate is the activator, and cadmium is removed. In many cases, a third fine purification stage is included.

The conventional hot – cold liquor purification process has a number of disadvantages:

1) The necessity of adding copper if too little copper is present in the starting materials
2) The possibility of releasing highly toxic arsine
3) The presence of the impurities arsenic and antimony in the precipitated copper
4) The possibility that the precipitated metals may redissolve

Figure 11. Reversed liquor purification [2, p. 608]

These disadvantages have led to the development of the alternative reversed liquor purification process (Fig. 11). Here, it is not necessary to add copper to remove cobalt and other impurities. The low concentrations of arsenic are sufficient to act as activator, the costly copper additions are avoided, and relatively pure cementates are obtained in both precipitation stages. This process can also be operated continuously, whereby the addition of zinc dust is controlled by measuring the electrode potential, which is a function of the copper and cadmium concentrations in the liquor.

5.7. Electrolytic Production of Zinc

[1–5], [10], [13]

Principles of Zinc Electrolysis. As the standard electrode potential of Zn^{2+} is -0.763 V, a solution of zinc sulfate should not deposit zinc on electrolysis: hydrogen should be liberated instead. Zinc deposition is only possible because of the hydrogen overvoltage at the zinc electrode, which causes a voltage shift of magnitude approximately equivalent to the standard electrode potential of zinc. The overvoltage is influenced by a number of factors. For example, the effect of current density is expressed by the Tafel equation:

$$\eta = a + b \log i$$

It decreases with increasing temperature, but, as the conductivity decreases with decreasing temperature, the energy consumption increases. With these effects in mind, two typical methods of performing zinc electrolysis were used in industry for a long time. Either the electrolytes were slightly acidic and current densities were ca. 325 A/m^2 or they were strongly acidic and current densities were ca. 850 A/m^2. The process parameters widely used today give good current yields in zinc electrolysis using current densities in the range 400 – 600 A/m^2 and a process temperature not exceeding 40 °C.

However, the hydrogen overvoltage is also influenced by the condition of the surface of the electrodes. Smooth surfaces lead to high overvoltages. For this reason, the cathode plate must be stripped every other day in practical operation. Zinc electrolysis is extremely sensitive to impurities in the electrolyte. These fall into several groups:

1) Impurities that are more electronegative than zinc, e.g., potassium, sodium, calcium, magnesium, aluminum, and manganese. These impurities do not directly interfere with the electrolytic process. If concentrations are

too high, the viscosity of the electrolyte increases and the diffusion processes in the boundary layers are disturbed. A limit of 60 g/L is used as a guideline figure.

2) Impurities whose electrode potential lies between those of Zn^{2+} and H^+. In the case of lead, cadmium, thallium, and tin, the hydrogen overvoltage is higher than that of zinc. These metals are deposited and form impurities in the zinc. In the case of iron, cobalt, and nickel, the overvoltage is lower than that of zinc. These are also deposited electrolytically but can be redissolved by the cell acid. Redox effects can lead to reduction in current yield. For this reason, the maximum tolerable concentrations are very low (see Section 5.6).
3) Impurities that are more electropositive than zinc. These include copper, arsenic, antimony, indium, tellurium, and germanium. These lead to a reduction in the overvoltage. The deposition of copper, nickel, cobalt, arsenic, and antimony can have a strongly detrimental effect on current yield due to the formation of local elements on the cathode, leading to dissolution of the zinc. For this reason, the maximum tolerable concentrations of these impurities are also very low, and the zinc electrolytes must therefore be rigorously purified.

The Practice of Zinc Electrolyis. Zinc electrolysis is a complex system in which positive and negative factors, especially as they affect current yield, energy consumption, required purity of the liquor, and mechanization, must be balanced against each other.

The purification of the liquor is now so well controlled that lower current densities can be used, enabling the electrolysis time between cathode changes to be extended from one to three days. Also, the cathode stripping operation, which involved heavy manual work, has been improved by the development of mechanical stripping equipment, and this has enabled cathodes with increased surface areas to be used.

In general, the electrolytic cells are concrete baths cast in one piece and lined with polyethylene. Lead linings are no longer used in modern electrolysis plants. The cells are arranged in rows and connected in series. The electrolyte supply to each cell is usually individually controlled.

The cathode plates consist of sheet aluminum (99.5 %), 5 – 7 mm thick, supported on carrier rods and provided with welded or plated copper contacts. The cathodes are polished at intervals of 4 – 6 weeks to prevent excessive adhesion of the cathode deposits. The latter problem can also be controlled by suspending the cathode plates in the bath and briefly running them as anodes.

Anode materials are usually Pb – Ag alloys with a silver content of 0.25 – 0.75 %. The anodes are usually made by casting the metal around a central copper carrier rod. Anodes that contain Sr and/or Ca and Ti in addition to Ag have higher strength and improved corrosion resistance.

5.8. New Developments in Zinc Production [2], [32]

Pressure Leaching of Sulfidic Zinc Concentrates. There have been many attempts to avoid the roasting process in the treatment of sulfidic zinc concentrates. For example, a process of pressure leaching of sulfidic concentrates has been developed by Sherritt Gordon Mines, Fort Saskatchewan, Alberta, Canada, and is used on an industrial scale.

The process can be represented by the equation:

$$ZnS + H_2SO_4 + 1/2\,O_2 \rightarrow ZnSO_4 + H_2O + S$$

which consists of the partial reactions:

$$ZnS + Fe_2(SO_4)_3 \rightarrow ZnSO_4 + 2\,FeSO_4 + S$$

$$2\,FeSO_4 + H_2SO_4 + 1/2\,O_2 \rightarrow Fe_2(SO_4)_3 + H_2O$$

Dissolved iron originates either from marmatitic blende (Zn, Fe)S or pyrrhotite Fe_7S_8, but not from pyrites FeS_2, which does not dissolve under these liquor conditions. This iron promotes the oxygen transfer reaction that converts the sulfide to sulfate.

The process is carried out in two stages, as shown schematically in Figure 12. The zinc concentrate is size reduced by wet grinding to 90 % <44 µm and oxidatively leached in two stages at 150 °C at an oxygen pressure of 1 bar. Exhausted electrolyte (cell acid) is used as solvent. In the

Figure 12. Pressure leaching of zinc concentrate [2, p. 610]
a) Pressure leaching, stage 1; b) Thickener; c) Pressure leaching, stage 2; d) Washing; e) Iron precipitation; f) Filtration; g) Cleaning tank; h) Electrolysis

first stage, 80 % of the zinc present is dissolved, and in the second stage a further 18 %.

The overflow from the thickener in the first stage, at a pH of 1.5 – 2.5, is treated with zinc oxide to neutralize the residual iron that was not precipitated in the autoclave, and the liquor so obtained is filtered and purified in the usual way. It is then fed to the zinc electrolysis stage.

The residue from the first stage is pumped together with cell acid into the autoclave of the second stage. After solid – liquid separation, the solution from the second stage is recycled to the first autoclave. The residue is washed in countercurrent flow to remove elemental sulfur if necessary, and the residual iron oxide is treated to recover lead and noble metals or disposed of, depending on its composition.

The process is used in two Canadian zinc smelting plants, one in Trail (Cominco), and the other in Timmins (Texas Gulf) in Ontario.

Direct Leaching of Oxidic Zinc Ores [2]. Some new methods of directly leaching oxidic ores (smithsonite, willemite, etc.) have been developed.

A willemite containing 40 % zinc has been directly leached at the zinc smelting plant at Trés Marias of the Companhia Mineira de Metais in Brazil. Smithsonite with a lower zinc content (<30 %) is first enriched by treatment in a Waelz kiln, and the oxide obtained is then leached.

6. Uses and Economic Aspects

Two properties of zinc are of special relevance to its applications. Firstly, its standard electrode potential is considerably more positive than that of the construction material iron. Zinc coatings therefore provide very good corrosion protection for steel structures. Secondly, zinc has a relatively low melting point, which makes it suitable for use in pressure die casting of complex components.

6.1. Galvanizing [3], [33]

The ever-increasing need to make the best use of the world's raw material reserves means that corrosion prevention as a method of preserving the usefulness of commercial metals continues to increase in importance. Moreover, as the atmosphere becomes increasingly corrosive, standards of corrosion protection must continue to rise, especially in steel construction.

A zinc coating on steel ensures lasting protection against the corrosive effects of the weather by the following mechanisms:

1) The effect on zinc of the carbon dioxide and moisture in the air is to form protective coatings with a zinc carbonate basis, resulting in a low corrosion rate

2) Because of its electrochemical property of providing cathodic protection, zinc actively prevents the occurrence of corrosion in the region of small defects, damaged areas of coating, and cut edges of sheet

In the industrialized countries, almost 50 % of the zinc consumed is used for corrosion protection.

Commercial zinc (98.5 – 99.5 %) is usually used for hot-dip galvanizing in production and jobbing plants, and high-purity zinc (99.95 %) for the continuous galvanizing of steel strip or wire. The metallurgical processes used to produce the less pure grades of zinc mean that lead is the main impurity present. This is an advantage, as the presence of 1 % lead reduces the surface tension of zinc by ca. 40 % compared with that of the high-grade product. The components being galvanized are therefore more effectively wetted by the molten zinc.

During the process of immersion in the zinc bath, which takes only a few minutes, the component is heated to ca. 450 °C. Diffusion processes cause layers of iron – zinc alloys to form on the steel surface, giving very good adhesion of the zinc coating.

Other galvanizing processes have been developed in addition to the hot-dip process. In electrolytic galvanizing, a d.c.current causes the deposition of lustrous coating, 5 – 25 µm thick, from acidic, cyanide, or alkaline cyanide-free electrolytes. However, these only give protection against mildly corrosive media. In general, additional protection is provided by chromate passivation.

In the spray galvanizing process, zinc wire is melted in a fuel gas/oxygen flame or an electric arc at the jet of a spray pistol and is propelled by compressed air from a distance of 15 cm, giving a coating ca. 0.1 mm thick. The resulting purely mechanical adhesion of the zinc is inferior to that produced by alloy formation at the metal interface in hot-dip galvanizing.

6.2. Zinc as a Construction Material [2], [34]

Although zinc has fairly good strength properties, it was for a long time not used as a material of construction because of its very poor creep resistance. Low-alloy zinc grades based on Zn – Ti – Cu, which have very good ductility and creep resistance, were developed only ca. 40 years ago. This material can be rolled to form zinc plate or sheet which can be used in the manufacture of roof drainage components or for covering buildings. A wide range of shapes has been developed, enabling aesthetic appeal to be combined with protection of buildings from the rigors of nature.

6.3. Pressure Die Casting with Zinc [2], [35]

Pressure die casting is another major area of use and is dominated by alloys of the type ZnAl4Cu1 and modifications thereof.

Some of the advantages of zinc for pressure die casting are:

1) Production runs can be very large (60 – 1000 components), depending on the size and complexity of the components
2) The dies are extremely durable, enabling up to 10^6 components to be produced from one die
3) The low viscosities and low melting points of the alloys ensure a high definition product
4) Dimensional accuracy is ensured as shrinkage of the zinc alloys is low and easily controlled
5) Lustrous or matt surfaces can be obtained with various metallic coatings and effects
6) Costs are low due to large production runs
7) The products are durable because of their good mechanical and physical properties
8) The energy requirements of manufacture are low

Approximately 50 % of all zinc pressure die castings go to the automobile industry.

6.4. Zinc as a Chemical [2], [36]

Zinc-based chemicals, including zinc dust, account for ca. 12 – 15 % of world zinc consumption. Zinc oxide is quantitatively by far the most important zinc-based chemical product, followed by zinc dust, zinc sulfate, and zinc chloride in order of importance and quantity. All other zinc compounds are of minor importance.

World consumption figures for zinc oxide and zinc dust have remained constant for many years. However, the demand for zinc sulfate and chloride is decreasing. The rate of growth of the consumption of zinc thiocarbonate and zinc stearate matches that of rubber production, their main area of use. Zinc oxide, the compound most in demand, can be produced by various processes. Its purity and quality depend on the production method used. In the indirect (so-called French) process, pure zinc is heated and oxidized in a current of air. The very pure zinc oxide formed is collected as a powder in settling chambers where it separates into different particle sizes. This material is usually known as zinc white. In the direct (so-called American) process, the raw materials used are zinc ores or zinc byproducts, which usually contain lead. A carbonaceous material is heated with the raw material, reducing it with formation of zinc vapor. This is oxidized with air and separated into particle size fractions.

The starting materials for wet chemical processes are solutions of purified zinc. Zinc carbonate or hydroxide is precipitated and is then filtered, washed, dried, and calcined at ca. 800 °C.

The various types of zinc oxide include an industrial grade, which is used as an intermediate product in the production of other chemicals; pigment grades, which include almost all the lead-containing grades; precipitated zinc oxides which have no pigment properties; and special grades such as the extremely finely-divided zinc oxide for photocopying paper.

The main consumer of zinc oxide is the rubber industry, in which it is used as a vulcanization activator and sometimes also as a filler.

Zinc oxide as a pigment in aqueous latex paints has lost a significant share of the market. Its use in agriculture as an additive to fertilizers to treat zinc deficiency in soils is of lesser importance. Zinc oxide is a component of formulations in the glass, enamel, and ceramic industries, where it influences the melting point and also the optical and elastic properties, color, and luster of the glaze. It is also a component of face powder, lipsticks, and creams used in the cosmetics industry. It is also used as an additive to lubricants, adhesives, drying agents, and delustering agents, and as a catalyst in methanol synthesis.

Zinc dust is produced by a similar process to that used for zinc oxide, but in a reducing atmosphere. There are two grades: pigment zinc dust and zinc dust for chemical use. Zinc dust is used as a pigment for anticorrosion paints and coatings whose primary function is to form an impermeable surface. The action of the environment leads to the formation of zinc carbonate and basic zinc compounds between the zinc particles, reinforcing this effect. These coatings also give cathodic protection, which is especially useful if there is slight damage to the coating layer.

6.5. Economic Aspects

The development of world zinc consumption in the important industrial countries and regions of the world is illustrated by the figures for the years 1980, 1985, and 1990, which are listed in Table 4.

Based on the article Zink-Legierungen in Ullmann's, 4th ed., written by MANFRED PÖTZSCHKE

1. Introduction

Zinc recrystallizes just above room temperature and has low creep resistance. It is therefore only suitable as a construction material when alloyed. The alloying elements, mainly Al, Cu, Ti, and Mg, cause grain refinement, mixed crystal formation, or precipitation hardening, thereby considerably improving the mechanical properties.

The properties of zinc alloys are largely determined by the hexagonal structure of zinc (*c/a* ratio 1.856). The physical and mechanical properties and plastic deformation behaviour vary with the orientation with respect to the principal hexagonal axis (anisotropy). There can also be marked texturization due to casting and deformation, such that characteristic values depend on the direction of the deformation. No significant hardening occurs on cold working, as recovery and relaxation take place rapidly. Recrystallization by seed formation begins at temperatures in the range 100 – 300 °C and above, depending on the alloy type.

The industrial zinc alloys combine outstanding metal forming properties with a well-balanced range of application properties. Casting alloys can be machined and ductile alloys can be formed using standard methods in each case.

Corrosion Behavior. Zinc alloys can be coated by the usual methods of electroplating, vapor deposition, or painting. Corrosion resistance can be improved by chromating or phosphating. The alloys are amphoteric, dissolving in acids and strong alkalis. They are therefore widely used under mildly corrosive conditions, e.g., in water or solutions whose pH is in the range 6 – 12.5, and in the atmosphere. Strongly adherent insoluble (basic) coatings of hydrozincite are formed which inhibit further attack. Depending on the aggressiveness of the atmosphere, the annual corrosion rate can be between 1 – 4 µm (rural air) and 4 – 13 µm (industrial air) [2], [3].

Zinc undergoes galvanic corrosion by ions of more noble metals (e.g., copper), and contact corrosion can lead to pitting, although in structures in which zinc alloys are in contact with aluminum, iron, or stainless steel components, contact corrosion does not occur as the difference in electrode potential is too small.

If foreign elements originating from the zinc ore, e.g., Pb, Cd, Sn, In, or Tl, are present in Zn – Al alloys, there is a tendency to intergranular corrosion. This can be limited to some extent by adding Mg. This tendency is the reason why zinc alloys only became widely used when it became possible to produce high-grade zinc (99.99 – 99.995 %, DIN 1706) on an industrial scale in the mid-1930 s. Stress corrosion of zinc alloys is not observed.

Monographs are available on the corrosion behavior of zinc exposed to the atmosphere [4], in water [5], and in the presence of chemicals [6] and bitumen [7].

Methods of measuring the corrosion of zinc alloys are given in the following standards. (see below)

Also, tests are carried out in atmospheres saturated with water vapor and in autoclaves to simulate the behavior of castings exposed for long periods. Both tests also give information about casting defects in the surface.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a28_531

DIN 50 017	Corrosion in damp-heat atmospheres
DIN 50 018	Corrosion by condensates: changeable climates with SO_2-containing atmospheres
DIN 50 021	Corrosion by mist sprays of various sodium chloride solutions
DIN 50 956	Tests of porosity of coatings on zinc and zinc alloys: copper sulfate method
DIN 50 958	Corrosion testing of chromated articles: modified Corrodkote method

Material Properties. Testing of zinc alloys is regulated not only by national and international standards, but also by the industry standards of the European zinc producers, e.g., for the following tests:

1) Tensile testing of sheet and strip under uniaxial stress
2) Tensile testing of pressure die cast test pieces (DIN 50 148)
3) Vickers or Brinell hardness testing (DIN 50 351)
4) Flat bending fatigue test on sheet, strip, and pressure die cast test pieces (DIN 50 100)
5) Notched bar (Charpy) impact test (DIN 50 116, July 1982)
6) Folding behavior

The material tests also measure variations in some characteristic values with testing rate, an effect typical of zinc alloys. For example, tensile strength increases with increasing strain rate, while elongation decreases.

A comprehensive metallographic atlas of zinc and zinc alloys has been produced by the European zinc manufacturers [8].

2. Casting Alloys

ZnAl(Cu) Alloys. Standard specifications for casting alloys are given in DIN 1743 (April 1978) Sheet 1 (ingots) and Sheet 2 (castings). The main alloying elements are Al, Cu, and Mg, and the zinc has a purity of 99.99 – 99.995 % (DIN 1706). The solubility of Al in Zn in the solid state is only 0.2 wt % (see Zn – Al phase diagram, Fig. 1), and that of Cu 2.7 wt %. The decreasing solubility of both alloying elements with decreasing temperature causes segregation processes and hence grain refinement and a considerable improvement in the mechanical properties, especially tensile strength, hardness, and impact strength. Aluminum lowers the solubility of Fe, so that molten Zn can be melted and kept molten in iron vessels. The Mg addition (up to 0.06 wt %) inhibits intercrystalline corrosion and compensates for the harmful effect of companion elements (DIN 1743). It also increases the hardness.

Figure 1. Zn – Al phase diagram

Typical of ZnAl and ZnAlCu alloys is the eutectoid structural transformation in the two-component system (beta decomposition of the Al-rich mixed crystal) or phase transformation of the Γ-phase in the three-component system. Both phenomena cause dimensional changes and deterioration of mechanical properties (aging), but do not affect the technical application properties.

Table 1 lists the ZnAl(Cu) alloys, some specified in DIN 1743, with their designations, material properties, compositions, and typical applications. For pressure die casting (indicated by the letters GD), alloys containing ca. 4 wt % Al and ca. 1 wt % Cu (Z 410) and Cu-free alloys containing ca. 4 wt % Al (Z 400) are used. In Germany, the alloy Z 410 accounts for 90 % of total consumption, whereas ca. 90 % of U.S.

consumption is of Cu-free alloy. The standard alloys for sand casting (indicated by S) or gravity die casting (indicated by GK) include those containing 4 wt % Al and 3 wt % Cu (Z 430) and the quasi-eutectic alloy containing 6 wt % Al and 1 wt % Cu (Z 610). Other alloys containing 8, 12, and 27 wt % Al (ZA 8, 12, and 27) have been developed as casting and forging alloys for special applications. There is also an alloy containing 30 wt % Al and 5 wt % Cu for use in plain bearings.

Uses and Casting Methods (see also → Foundry Technology). High-purity or fine zinc (FZn) alloys are mainly used in automatic pressure-die casting plants, in which a measured quantity of molten alloy at 390 – 420 °C (the casting temperature) is rapidly injected at high pressure into a steel die with a temperature of 160 – 200 °C. The cast component so formed is dimensionally very accurate and requires very little treatment to remove sprue and flash. The cast components have an excellent surface finish which can be further improved electrolytically, chemically, or by coating with organic materials. In Germany, ca. 10^{10} cast components are produced annually. The smallest components, with wall thicknesses of 0.3 – 1.0 mm, can be produced at rates of 500 – 5 000 shots per hour, and medium sized components with wall thicknesses of 1.0 – 2.0 mm at 100 – 400 shots per hour. (Note that dies with several cavities, i.e., multiple dies, can produce several components per shot.) Large components with wall thicknesses of 1.2 – 3.0 mm can be produced at the rate of 60 – 150 components per hour. The steel dies have a working life of 500 000 – 5 000 000 shots. Cavities and recesses in the components can be cast directly.

Pressure die casting is an economical process which enables complex components to be produced. The small wall thicknesses cannot be produced by any other casting process or casting alloy. Even so, wall thicknesses of >50 mm can also be obtained.

The dies are hardened permanent molds of high-grade hot-forming tool steel. Gating technology in pressure die casting is based on the latest findings of fluid mechanics. Molten-metal flow rates can reach 80 m/s.

Zinc pressure die castings have a wide range of uses as components in the automobile indus-

try, bicycle and motor car wheels, machinery and equipment, vending machines, office machines, domestic appliances, precision equipment, electrical technology, and a wide range of everyday utensils.

Sand and gravity die casting of zinc alloys is preferable to pressure die casting if the number of castings required does not justify manufacture of dies. In sand casting, the patterns can be made of wood, gypsum, metal, or plastics. Casting temperatures are 420 – 480 °C for Z 430, and 390 – 420 °C for the quasi-eutectic alloy Z 610. The shell or Croning process can also be used.

Gray iron molds are suitable for gravity die casting. The castings obtained have a smoother surface than those produced by sand casting. Casting temperatures are the same as those for sand casting. Mold temperatures are usually in the region of 200 °C. Sheet metal pressing tools are manufactured by zinc casting. These can be accurately cast, minimizing fettling costs. The self-lubricating properties of zinc are utilized in sheet metal pressing.

3. Ductile Alloys

ZnCuTi Alloys. Pack-rolled ductile zinc alloys based on commercial zinc (purity 98.5 – 99.5 % Zn, the rest mainly Pb) were produced until the mid-1960 s. This was followed by rapid developments that led to the production of rolled strip ZnCuTi materials (titanium zinc) in which the principal component was high-purity (99.995 %) zinc. Titanium zinc is a zinc alloy in accordance with DIN 17 770, containing 0.1 – 0.8 wt % Cu, 0.08 – 0.15 wt %Ti, and 0.002 – 0.01 wt % Al. It is dispersion-hardened "in situ", the dispersoids being the intermetallic compounds $TiZn_{15}$ and ε-Zn – Cu. A combination of alloying, rolling, and heat treatment leads to materials with relatively high creep strength (creep limit $\geq$50 N/mm^2 for 1 %/a elongation), good mechanical properties (tensile strength $\geq$150 N/mm^2, 0.2 % offset yield stress $\geq$100 N/mm^2), high ductility (fracture strain $\geq$40 %) and good working properties (e.g., solderability). They are mainly used in the building industry for roof drainage systems, flashing, and non-load-bearing profiles. Using a special technique, titanium zinc can be deep drawn like brass or steel.

Other Ductile Alloys. Etched plates of FZn – Al – Mg alloys (ca. 0.01 wt % Al, ca. 0.05 wt % Mg) are used for graphic letterpress printing, FZn-Pb-Cd alloys (0.03 – 1.0 wt % Pb, 0.03 – 1.0 wt % Cd) for the negative electrodes of primary cells, and FZn – Mn alloys (up to 1.0 wt % Mn) for stampings.

During World War II, zinc hot pressing alloys and zinc conductors were used as substitutes for other nonferrous metals, and high-Al alloys were sometimes used as low-temperature alloys.

Superplastic ductile Zn – Al alloys containing, e.g., 4 or 22 wt % Al (trade name Zilôn) have become of some industrial importance. Titanium zinc has superplastic forming properties under certain conditions.

Forging alloys (Zn – Al alloys containing 12 or 27 wt % Al) are used in special applications.

4. Zinc Alloys for Special Applications

Zinc performs an extremely important function in preventing the corrosion of steel, and a series of special zinc alloys (mainly based on commercial zinc, DIN 1706) have been developed for hot-dip galvanizing or for use in cathodic corrosion protection:

1) Zinc containing 0.05 – 0.3 % Pb and 0.15 – 0.35 % Al (Sendzimir galvanizing)
2) Zinc alloy containing 55 % Al and 1.0 % Si (Galvalume, Zincalume)
3) Zinc alloy containing 5 % Al and 0.1 % SE (Galfan)

Master alloys for hot-dip galvanizing:

1) Zinc alloy containing 4.5 % or 9 % Al
2) Zinc containing 0.05 % Al, 0.008 % Mg, 0.15 % Sn (Polygalva for galvanizing Si-containing steel)
3) Zinc having 1 % Pb and reduced Cd content (0.05 wt % Cd) for pipes for potable water (DIN 2444)

Anodes for cathodic corrosion protection: Zinc with "activating" additives, e.g., Al, Cd.

5. Economic Aspects

The pattern of consumption of zinc in the western world and in Germany in 1991 is given in the following:

Castings	117 600 t
Brass production	114 000 t
Galvanizing	92 800 t
Semifinished products	95 000 t
Chemical products (including dust and powder)	23 100 t
Others	7 400 t

Western World consumption was 5.36×10^6 t, and total World production was 6.89×10^6 t.

1. Zinc Halides

1.1. Zinc Fluoride

Zinc fluoride [*7783-49-5*], ZnF_2, M_r 103.37 forms monoclinic tetragonal crystals with the rutile structure [1], *mp* 872 °C [2], ϱ_{25} 4.95 g/cm^3. The solubility of $ZnF_2 \cdot 4\,H_2O$ at 20 °C is only 1.62 g ZnF_2 in 1000 mL solution, but it is very soluble in aqueous ammonia. ZnF_2 reacts with sodium hydroxide solution to form flocculant precipitates of basic zinc fluorides.

Synthesis. $ZnF_2 \cdot 4\,H_2O$ is formed when zinc carbonate or zinc oxide reacts with aqueuos hydrofluoric acid. The water of crystallization can be driven off by heating to >200 °C and/or in a vacuum.

Analysis. Calcined commercial zinc fluoride has the typical analysis 61 – 63 % Zn, and 33 – 36 % F, with the following maximum impurity levels: Fe 500 ppm, Pb 100 ppm, and SO_4 100 ppm.

Uses. Zinc fluoride is used as an additive to electrolytic galvanizing baths, in glazes and enamels for porcelain, and special types of glass with a high refractive index. It is also used as a flux for welding and soldering and as a fluorinating agent in organic syntheses.

1.2. Zinc Chloride

Zinc chloride [*7646-85-7*], $ZnCl_2$, M_r 136.29 forms hexagonal-rhombic crystals, usually in the form of a white powder, *mp* 283 °C, *bp* 732 °C, ϱ 2.91 g/cm^3 at 25 °C, which is very soluble in water (432 g $ZnCl_2$ in 100 g water at 25 °C, 615 g $ZnCl_2$ in 100 g water at 100 °C). It is also soluble in alcohols, ether, acetone, ethyl acetate, glycerine, pyridine, amines, and nitriles.

Zinc chloride is strongly hygroscopic and forms hydrates with 1 – 4 mol water. It has a strong affinity for water, and causes many organic compounds to undergo condensation reactions. Considerable heat is evolved when $ZnCl_2$ dissolves in water.

Zinc chloride reacts with NH_4Cl to form the compounds $(NH_4)_2[ZnCl_4]$, $(NH_4)_3[ZnCl_5]$, and $(NH_4)_4[ZnCl_6]$. Analogous compounds are formed with amine hydrochlorides. Ammonia forms complexes with the composition $[Zn(NH_3)_xCl_2]$ ($x = 2, 4, 6$). Amines give analogous compounds. In water, zinc chloride behaves as an acid, forming aquoacids with the compositions $H[ZnCl_2OH]$ and $H_2[ZnCl_2(OH)_2]$. With increasing dilution, the aquoacid anions take up water and lose Cl^-, eventually being converted into the aquocation complex $[Zn(H_2O)_6]^{2+}$ and losing the strongly acid reaction.

Commercial zinc chloride often contains basic zinc salt which leads to cloudiness in aqueous media.

Production. High-purity zinc chloride is formed from zinc and HCl gas at 700 °C [3]. Spectroscopically pure zinc chloride can be obtained by decomposing zinc amalgam with HCl [4]. Quality specifications are listed in Table 1.

Table 1. Quality specifications for zinc chloride

	Analytical-grade $ZnCl_2$ (ACS, ISO)	High-purity $ZnCl_2$ (DAB, PhEur, BP, JP, USP)
Assay (complexometric)	≥98 %	98 – 100.5 %
pH (10 % aq.)		4.6 – 5.5
SO_4	≤0.002 %	<0.01 %
Total N	≤0.001	<0.01 %
As		<0.0002 %
Ca	≤0.001 %	<0.01 %
Fe	≤0.0005 %	<0.001 %
K	≤0.001 %	0.001 %
NH_4	≤0.001 %	0.02 %
Na	≤0.001 %	
Oxychloride (as ZnO)	≦1.2 %	in accordance with test

Technical-grade zinc chloride is usually produced by leaching zinc oxides or zinc-containing waste such as zinc dross or ammonium chloride slags (unavoidable byproducts of hot-dip galvanizing) with hydrochloric acid. Raw materials containing a high percentage of NH_3 must be subjected to an additional treatment stage, i.e., passing chlorine gas into the aqueous suspension to oxidize the ammonia to nitrogen.

The zinc-containing raw materials are dissolved in concentrated hydrochloric acid. The crude liquor contains varying amounts of the elements Fe, Mn, Pb, Cu, and Cd. Fe^{2+} is oxidized to Fe^{3+} with H_2O_2 or $KMnO_4$, and $Fe(OH)_3$ is precipitated at pH 4 – 5. Also, the Mn is precipitated as MnO_2 by $KMnO_4$. The remaining elements Cu, Pb, and Cd are removed by treatment with zinc dust (cementation). The solution is then evaporated to dryness. Aqueous solutions are sometimes subjected to further processing.

Uses of zinc chloride:

1) Hydrochlorination of ethanol to monochloroethane

$$C_2H_5OH + HCl \rightarrow C_2H_5Cl + H_2O$$

2) Catalytic hydrolysis of benzotrichloride to benzoyl chloride
3) Catalyst in the production of ammonium methylene-bis-dithiocarbamate from hydrogen peroxide, aqueous ammonia, carbon disulfide, and ethylenediamine
4) Production of benzyl chloride from benzene, formaldehyde, and $HCl/ZnCl_2$
5) Filling material for batteries, emulsion breaker in petrochemical processes, deodorizing agent
6) Production of zinc compounds, e.g., zinc cyanide from potassium cyanide and a solution of zinc chloride (sometimes zinc sulfate)
7) Production of zinc soaps from alkali metal soaps and zinc chloride

1.3. Zinc Bromide

Zinc bromide [*7699-45-8*], $ZnBr_2$, M_r 225.21, forms colorless rhombic crystals, *mp* 394 °C, *bp* 650 °C, ϱ 4.29 g/cm^3, which are strongly hygroscopic. The dihydrate, $ZnBr_2 \cdot 2\,H_2O$, M_r 261.24, melts at 35 – 47 °C with loss of water of crystallization. It is obtained by dissolving an aqueous suspension of ZnO or metallic zinc in aqueous HBr. Anhydrous $ZnBr_2$ is formed from its elements at ca. 600 °C or by thermal dehydration of the dihydrate in a stream of dry CO_2. Its solubility in water at 25 °C is 820 g/L.

Uses of zinc bromide:

1) A mild Lewis acid for alkylation reactions [5]
2) A catalyst for intramolecular reactions [6]
3) An activating agent in the production of activated carbon
4) An additive to photographic gelatins
5) An electrolyte for zinc bromide batteries

High-purity $ZnBr_2$ contains ≥98 % $ZnBr_2$, with the following maximum impurity contents: Ba 10 ppm, Ca 100 ppm, Fe 10 ppm, K 100 ppm, Mg 100 ppm, and Na 100 ppm.

1.4. Zinc Iodide

Zinc iodide [*10139-47-6*], ZnI_2, M_r 319.22, forms white to yellowish cubic crystals, *mp* 446 °C, *bp* 624 °C, ϱ_{25} 4.73 g/cm^3. It is produced by adding metallic zinc to constant-boiling aqueous hydriodic acid until the yellow color disappears, by neutralizing aqueous HI with ZnO in the presence of a catalyst (precipitated silver), or by the reaction of I_2 vapor with molten zinc at 600 °C in a stream of N_2

[7]. Its solubility in water at 20 °C is 4500 g/L (hygroscopic).

Zinc iodide is used in medicine as a topical antiseptic astringent and in the preparation of iodide – zinc – starch solution.

2. Zinc Sulfate

Zinc sulfate [*7733-02-0*], $ZnSO_4$, M_r 161.44, ϱ 4.33 g/cm^3, forms rhombic crystals. On heating to >650 °C, zinc sulfate undergoes considerable decomposition with formation of basic sulfates. Above 800 °C, it decomposes completely into ZnO and SO_3.

$ZnSO_4$ is very soluble in water, and forms hydrates with 1, 2, 4, 6, and 7 molecules of water of crystallization. The hepta-, hexa-, and monohydrates are produced on an industrial scale.

Zinc sulfate heptahydrate [*7746-20-0*], $ZnSO_4 \cdot 7\,H_2O$, M_r 287.55, forms white, lustrous, columnar, rhombic crystals. It is transformed into the hexahydrate at 39 °C. It occurs in nature as goslarite. Mixed crystals are formed with the sulfates of Fe, Mg, Mn, Co, and Ni. It is very soluble in glycerine, but only sparingly soluble in other organic solvents.

Zinc sulfate is obtained by leaching zinc-containing materials with sulfuric acid in an aqueous medium. Suitable materials include zinc dross, slags, sweepings, oxides, sludges, metallic zinc, and zinc-containing flue dusts [8]. Used sulfuric acid can be utilized. It should be noted that arsine can be formed during the treatment of metallic dross and waste. Iron, manganese, and heavy metals are removed by the same process as that used to treat electrolyte liquors.

The purified solution of zinc sulfate is evaporated until its density reaches ca. 1.4 at 80 °C. On cooling, crystals of zinc sulfate heptahydrate form and are centrifuged off. The crystals obtained are sometimes dried at ca. 30 °C to prevent efflorescence.

Pharmaceutical-grade $ZnSO_4 \cdot 7\,H_2O$ can be produced from sulfuric acid and pharmaceutical-grade zinc oxide. The impurity levels in the various grades of zinc sulfate are listed in Table 2.

Zinc sulfate monohydrate [*7446-19-7*], $ZnSO_4 \cdot H_2O$, is produced by thermal dehydration or by dehydrating with 95 % ethanol. It crystallizes from a zinc sulfate mother liquor at temperatures above 70 °C [9]. It can be dried in a rotary, spray, or fluidized-bed driers.

Uses of zinc sulfate can be divided into direct and indirect uses.

Direct uses:

1) Precipitating baths for viscose manufacture
2) Electrolytes for galvanizing baths
3) Additive (trace element) in fertilizers and animal feeds
4) In medicine, as an emetic, astringent, or disinfectant
5) Wood preservative, additive for paper bleaching, flocculant
6) Water treatment

Indirect uses:

1) Starting material for the production of other zinc compounds such as the fungicides Zineb and Mancozeb (→ Fungicides, Agricultural, Chap. 6.3.), zinc soaps (→ Metallic Soaps, Chap. 5.10.), and the antidandruff agent zinc pyrithione
2) Production of lithopone and zinc sulfide pigments
3) Production of zinc cyanamide from potassium cyanamide
4) Production of zinc phosphides

3. Toxicology and Occupational Health

Zinc metal and most of its compounds show very low toxicity compared to most other heavy metals. The toxicity of zinc salts varies to a certain extent, being dependent primarily on the toxicity of the anionic part of the compound. For example, the high toxicity and carcinogenicity of zinc chromate, $ZnCrO_4$, is not due to Zn^{2+}, but to the anionic CrO_4^{2-} component.

Intoxications with zinc and its compounds are comparatively rare. They can occur by ingestion of food contaminated with zinc leached from food containers or by inhalation of zinc or zinc oxide dust under occupational conditions (see below).

On the other hand, zinc is one of the most important essential elements for humans and all

Table 2. Commercial grades of zinc sulfate

	Analytical-grade $ZnSO_4 \cdot 7\,H_2O$	High-purity $ZnSO_4 \cdot 7\,H_2O$ (DAB, USP, PhEur, FCC)	Pure $ZnSO_4 \cdot 7\,H_2O$
Assay	≤99.5 %	99.5 %	98 %
pH (5 %, 20 °C)	4.4 – 5.6	4.4 – 5.6	
As	0.5 ppm	2 ppm	10 ppm
Ca	10 ppm	50 ppm	
Cd	2 ppm	2 ppm	30 ppm
Cu	5 ppm	1 ppm	10 ppm
Fe	5 ppm	10 ppm	30 ppm
K	10 ppm	100 ppm	
Mg	10 ppm	50 ppm	
Mn	2 ppm	10 ppm	50 ppm
Na	50 ppm	1000 ppm	
Pb	5 ppm	5 ppm	50 ppm
Chloride	5 ppm	100 ppm	4000 ppm
Hg		1 ppm	
Se		5 ppm	

forms of plant and animal life. It is necessary for growth, skin integrity and function, testicular maturation, immunocompetence, wound healing, and for a variety of metabolic processes including carbohydrate, lipid, protein and nucleic acid synthesis or degradation. It is an essential, coenzyme-like component for the function of more than 70 metallo-enzymes, including alcohol dehydrogenase, carbonic anhydrase, and carboxypeptidase [10]. Physiological amounts of zinc have been shown to decrease the toxicity of other heavy metal ions such as Cd, Hg, Pb, and Sn [11].

Biological significance, biochemistry, toxicokinetics, human and animal toxicity, levels of tolerance, detoxification, evaluation of health risks to humans, and ecotoxicity of zinc and its compounds have been reviewed [11–14].

Toxicokinetics. As an essential element, zinc is absorbed in an active transport process, regulated by dietary zinc status and occurring primarily in the ileum [15]. Zinc is bound to proteins to a large extent. Excretion occurs predominantly via the feces, and to a minor extent via urine and sweat. Excretion in the urine is up to 12.2 mmol/d; higher values indicate zinc intoxication [16].

Zinc is the most prevalent metal ion in human tissues other than blood. The body of a 70-kg man contains ca. 2.3 g of zinc [17], 64 % of which is found in muscle and 28 % in bone [18]. The highest zinc concentrations are found in reproductive organs, especially the prostate gland (87 µg/g wt weight), whereas the whole-body average is 33 µg/g wet weight [17]. Serum contains 10.7 – 22.9 mmol/L, plasma 17.4 ± 1.8 mmol/L, erythrocytes 184 – 198 mmol/L, and hair 3.30 ± 1.33 mmol/g [16].

Acute Toxicity. In contrast to numerous other heavy metals, zinc shows low acute toxicity. Zinc overload of the organism is rather unlikely and occurs almost exclusively by ingestion when food or drinks, especially acidic ones, are prepared or stored in galvanized containers [19], [20].

Symptoms of acute intoxication are gastrointestinal distress, diarrhea, nausea, and abdominal pain. Vomiting occurs almost universally. In elemental-zinc overdose, symptoms such as lethargy, slight ataxia, and difficulty in writing also appear. Abnormal laboratory parameters include increase of pancreatic enzyme activities, hypokalemia secondary to acute pancreatitis, and microhematuria [21], [22].

Zinc chloride, $ZnCl_2$, is caustic to the gastrointestinal tract, occasionally leading to hematemesis, beside the symptoms mentioned above. Furthermore, it is extremely detrimental to the lungs. An episode of pulmonary exposure to $ZnCl_2$ smoke resulted in ten fatalities due to pulmonary toxicity. Most survivers showed lacrimation, rhinitis, dyspnea, stridor, and retrosternal chest pain. In two autopsies, severe inflammation of the upper respiratory tract mucosa and pulmonary edema, but no changes in liver and kidneys, could be detected [23].

Zinc or zinc oxide fume is responsible for a syndrome which may occur in welding, galvanizing, or smelting operations, called "metal fume fever". Symptoms such as rapid breathing, dyspnea, cough, fever, shivering, sweating, chest and leg pain, myalgias, fatigue, metallic taste, salivation, thirst, and leukocytosis appear within 4 – 6 h after exposure and disappear after 24 – 48 h [24], [25]. The X-ray of the chest is normally clear. A rapid tolerance (tachyphylaxis, "quick immunity" [26]) develops in workers within 48 h, but may the lost over the weekend ("monday morning fever"). Metal fume fever can also be caused by exposure to fumes of aluminum, antimony, copper, iron, magnesium, manganese, and nickel.

Zinc phosphide, Zn_3P_2, is extremely toxic because of the formation of phosphine, PH_3, on reaction with water or acids.

Chronic Toxicity. The development of a toxicosis has been reported in the case of a continuous uptake of drinking water contaminated with 40 ppm Zn from a galvanized pipe [27]. Dialysis patients are at risk of an elevation of the plasma concentration of zinc (and other heavy metal ions) [28], [29]. The symptoms are similar to those of acute toxicity, but are less pronounced.

Genotoxicity. Zinc apparently does not show any mutagenicity or carcinogenicity [11]. In human lymphocytes, 0.1 – 1000 µmol/L of zinc acetate, alone or in combination with cadmium and lead acetates, failed to induce chromatid-type aberrations (deletions, acentric fragments) and gaps [30]. The carcinogenic effect of zinc chromate, $ZnCrO_4$, is due to the chromate anion, not to the zinc cation.

Reproductive Toxicity. There are no indications for reproductive effects, especially for teratogenicity, of zinc [11].

Immunotoxicity. There are no reports concerning immunotoxic effects of zinc. However, zinc chromate, $ZnCrO_4$, shows strong sensitizing effects and therefore is able to cause obstinate eczema under occupational conditions [31].

Toxicological Data. The lethal dose of $ZnCl_2$ in humans is 3 – 5 g. Since zinc sulfate, $ZnSO_4$, is less caustic than the chloride, it has lower toxicity [32].

Treatment. Decontamination of the gastrointestinal tract after oral uptake of zinc compounds by syrup of ipecac, lavage, or cathartics is mostly unnecessary, since patients usually vomit sufficiently. For normalization of zinc levels, $CaNa_2EDTA$ is the agent of choice [21], [23]. After oral uptake of $ZnCl_2$, milk may be administered to decrease absorption of the metal [34].

After contact of the skin with $ZnCl_2$, immediate removal is necessary using soap and plenty of water.

After contact of the eyes with $ZnCl_2$, adequate measures are rinsing with plenty of water, use of Isogutt eye drops, and contacting an ophthalmologist as soon as possible [34], [35].

In cases of $ZnCl_2$ fume inhalation, cortisone preparations should be applied immediately (e.g., by inhalation of Auxiloson) to avoid development of lung edema [35]. In severe cases clinical observation for at least 24 h is necessary.

Occupational Health. The MAK value of zinc oxide, ZnO, is 5 mg ZnO/m^3, measured as total fine dust [36]. The same TLV value has been set in Hungary, Japan, Poland, Sweden, and by the WHO, while it is 10 mg ZnO/m^3 in Bulgaria, Romania, and Pennsylvania (United States); it is 15 mg ZnO/m^3 in Finland. The United States has a TLV value of 1 mg $ZnCl_2$/m^3, and Massachusetts a 30-min limit of 0.2 mg/m^3 zinc chromate, $ZnCrO_4$ [17].

Zinc chromate, $ZnCrO_4$ is classified in group A 1 (proven human carcinogens) of Appendix III of the MAK list [36].

1. Zirconium

1.1. Introduction

On analyzing the gem mineral known as jargon from Sri Lanka, KLAPROTH in 1789 found it contained an oxide which he could not identify and which he later called " zirconerde". In 1824 BERZELIUS prepared the first zirconium metal, an impure black powder, by heating potassium hexafluorozirconate and potassium in a closed pot. LELY and HAMBURGER prepared the first relatively pure zirconium in 1904 by reduction of zirconium tetrachloride with sodium in a bomb, producing malleable, corrosion-resistant zirconium pellets. But it was a hundred years after BERZELIUS before VAN ARKEL, DE BOER, and FAST [1], [2] developed the iodide process which produced the first massive zirconium metal that could be cold worked and which exhibited good ductility at room temperature.

Early uses for zirconium metal were in pyrophoric devices such as fuses, ammunition primers, fireworks, photoflash powder, and flares. Zirconium powder was used extensively as a gettering material in vacuum tubes. By 1946 the consumption of zirconium for these purposes was about 5 t/a. Less than 50 kg of ductile iodide metal was sold, at ca. $ 700 per kilogram.

W. J. KROLL carried out the first inert-atmosphere magnesium reduction of zirconium tetrachloride in his Luxembourg laboratory in 1938 [3]. In 1944 the U.S. Bureau of Mines started a project to make ductile zirconium economically. KROLL was assigned to take over direction of the project in January, 1945. By 1947, a pilot plant was producing 30 kg of zirconium sponge per week. Concurrently, researchers at Massachusetts Institute of Technology and at Oak Ridge National Laboratory were evaluating the physical and atomic properties of metals as potential uranium fuel cladding materials for nuclear power stations. In 1948 hafnium-free zirconium was selected as most promising. By 1949 zirconium had been chosen as the structural material for the fuel core of the submarine thermal reactor, the land-based reactor prototype, and during 1949 – 1950 a satisfactory hafnium separation process was developed at Oak Ridge. By

10.1002/14356007.a28_543

the end of 1950, 3000 kg of hafnium-free zirconium metal strip had been produced, and the zirconium metal producing industry was launched as an integral part of the beginning nuclear power industry.

1.2. Properties

Physical Properties. Zirconium [*7440-67-7*] is a lustrous, strong, ductile metal similar in appearance to stainless steel. Pure zirconium metal has three solid phases: ω-Zr, which is stable below 200 K at ambient pressure and up to 1000 K at 6 GPa [4]; α-Zr, which is stable from 200 K to 1125 K; and β-Zr, which is the stable form between 1125 K and the melting point. These transition temperatures change with the addition of α- or β-stabilizing alloying elements. The important physical properties are presented in the following:

Relative atomic mass	91.224
Atomic radius	15.90 nm (in metal lattice)
Ionic radius (Zr^{4+})	7.5 nm
Electronegativity	1.22
Standard potential M/MO_2	1.53 V
Melting point	$1852 \pm 2\,^{\circ}C$
Boiling point	$3850\,^{\circ}C$
Crystal structure	
ω-Zr	hexagonal open
α-Zr	hexagonal dense, a = 32.3 mm, c = 51.5 nm
β-Zr	body-centered cubic, a = 36.1 nm
Transformation temperatures	
$\omega \rightarrow \alpha$	$-73\,^{\circ}C$
$\alpha \rightarrow \beta$	$862 \pm 5\,^{\circ}C$
Heat of fusion	2.30×10^4 J/mol
Heat of evaporation	5.96×10^5 J/mol
Electrical resistivity	$3.89 \times 10^{-5}\ \Omega \cdot cm$
Thermal conductivity	
at 25 °C	$21.1\ W\,m^{-1}\,K^{-1}$
at 100 °C	$20.4\ W\,m^{-1}\,K^{-1}$
at 300 °C	$18.7\ W\,m^{-1}\,K^{-1}$
Specific heat	
at 25 °C	$0.285\ J\,g^{-1}\,kg^{-1}$
at 865 °C	$0.335\ J\,g^{-1}\,kg^{-1}$
Thermal expansion coefficient	
α, bulk, at 25 °C	$5.89 \times 10^{-6}\ K^{-1}$
α-Zr, parallel to the C axis	$6.4 \times 10^{-6}\ K^{-1}$
α-Zr perpendicular to C axis	$5.6 \times 10^{-6}\ K^{-1}$
β-Zr	$9.7 \times 10^{-6}\ K^{-1}$
Density	
α-Zr	6.50 g/cm
β-Zr	6.05 g/cm
Effective cross section for thermal neutrons	$1.9 \times 10^{-29}\ m^2$ (0.19 barns)

Mechanical Properties. Although zirconium is a high-melting metal, its mechanical properties are similar to those of much lower melting metals: its elastic modulus is quite low, and its strength diminishes rapidly with increasing temperature. The mechanical properties of zirconium are strongly dependent on purity, especially the oxygen and nitrogen content, the amount of cold work, and the crystallographic texture. Forged or rolled zirconium shows marked anisotropy in mechanical properties in both the as-formed and annealed conditions. Pure zirconium is ductile at liquid-nitrogen temperatures but the metal is subject to hydrogen embrittlement whenever the hydrogen content sufficiently exceeds the hydrogen solubility at the operating temperature. Tables 1 and 2 gives typical values of the more important mechanical properties of zirconium and of Zircaloy 2 and Zircaloy 4 (see also Section 1.9).

Chemical Properties. Zirconium is a very reactive metal that, in air or aqueous solution, immediately develops a surface oxide film. This stable, adherent film is the basis for zirconium's corrosion resistance. In most media, zirconium is more resistant than titanium or stainless steel. Its acid resistance approaches that of tantalum, but unlike tantalum, zirconium is also resistant to caustic media.

Fluoride ions bond strongly to zirconium, and even a trace of fluoride in most media will drastically reduce its corrosion resistance.

The corrosion resistance in sulfuric acid is excellent at temperatures up to 150 °C and acid concentrations up to 70 %, except that welds and adjacent heat-affected zones are susceptible to corrosive attack above 60 % concentration. This can be alleviated by annealing. Ferric, cupric, and nitrate ion impurities in sulfuric acid decrease the corrosion resistance at acid concentrations above 65 %. Even at room temperature zirconium is rapidly attacked at concentrations above 75 %.

The corrosion resistance in hydrochloric acid is excellent at temperatures up to 130 °C and concentrations up to 37 %. However, even small amounts of ferric or cupric ions will lead to severe pitting and stress cracking.

The corrosion resistance in nitric acid is excellent at all concentrations up to 90 % and tem-

peratures up to 200 °C. In concentrations above 65 %, stress corrosion cracking may occur if high tensile stresses are present [5].

The corrosion resistance in phosphoric acid is excellent in all concentrations up to 65 °C, and, at concentrations below 40 %, up to 185 °C.

Zirconium is rapidly attacked by hydrofluoric acid, even at concentrations below 0.1 %.

The corrosion resistance in sodium hydroxide and potassium hydroxide is excellent at all concentrations, up to the boiling temperature. Zirconium is resistant to molten sodium hydroxide up to 1000 °C.

Zirconium is very resistant to most organic compounds at all concentrations and temperatures. But, when air or moisture are not available to reform the surface oxide film, zirconium is attacked by anhydrous chlorinated organics at elevated temperatures and is etched by bromine or iodine dissolved in anhydrous organics. Stress corrosion cracking may also occur.

Zirconium reacts with most gases at relatively low temperatures.

Zirconium forms a visible interference color film in air starting above 200 °C. Above 400 °C the adherent oxide film is black. Above 540 °C a loose gray-white oxide forms, the oxide layer becomes thicker as oxygen diffuses into the underlying metal, and the metal can become embrittled after prolonged exposure. The maximum continuous operating temperature of zirconium in air is ca. 450 °C. Short-term hot working such as forging, rolling, and extrusion are conducted at 550 – 1000 °C. Afterwards, the surface oxide and embrittled metal layer are mechanically and chemically removed. While solid zirconium metal is oxidized slowly in air, the oxidation is exothermic, and for high-surface-area forms, such as powder or sponge metal, the large heat release may cause ignition (see Section 1.8).

Oxygen-containing gases, such as carbon dioxide, carbon monoxide, sulfur dioxide, steam, and nitrogen oxides, oxidize zirconium somewhat slower than air. The maximum continuous operating temperature is about 400 °C.

Zirconium reacts more slowly with nitrogen than with oxygen because the reaction is less exothermic.

Zirconium readily absorbs hydrogen above 300 °C. The rate of absorption varies inversely with the thickness of the surface oxide film. Hydrogen solubility increases with temperature. On cooling, when the solubility is exceeded, zirconium hydride platelets precipitate, embrittling the metal. The reaction is reversible: hydrogen is removed on heating the metal above 600 °C in a high vacuum.

Zirconium's oxide film protects it from dry chlorine gas at room temperature, but any impact or abrasion that exposes a fresh metal surface may initiate an exothermic reaction producing zirconium tetrachloride vapor.

More information on the chemical behavior of zirconium metal can be found in [6].

1.3. Occurrence, Ores, and Mining

Zirconium is the ninth most abundant metal in the earth's crust, with an estimated concentration of 0.016 – 0.025 wt % [7], about one twentieth that of titanium but more plentiful than nickel, copper, or zinc. Zirconium occurs only in fully oxidized form, never as free metal.

There are over 40 known zirconium minerals which can be grouped:

1) Zirconium orthosilicates: Zircon and its metamict varieties
2) Zirconium dioxide: baddeleyite and its altered varieties
3) Zirconsilicates with sodium, calcium, iron, and other elements: eudialyte, eucolite, gittinsite and others
4) Zirconium carbonates with sodium, calcium, and other elements: weloganite and others
5) Others, including zirconolite ($CaZrTi_2O_7$)

Zircon is the predominant commercial zirconium mineral, but the minerals baddeleyite and eudialyte are also being used. All are obtained as byproducts of other mineral recovery operations.

Zircon [*1490-68-2*], $ZrSiO_4$, occurs as an accessory mineral in silica-rich igneous rocks, particularly granite, nepheline syenite, and pegmatite, and also in metamorphic and sedimentary rocks. Zircon is rarely found in rocks in economically minable concentration. Weathering and erosion of these rocks frees the zircon grains, and the combined action of rivers, seas, and wind concentrate the heavier minerals by natural gravitation processes in placer deposits, deltas, and ocean beaches. As an ore, zircon is recovered from unconsolidated sands in beach deposits.

Large heavy mineral sands deposits are being extensively mined in Florida, West Australia, South Africa, India, Russia and Kazakhstan, with smaller operations in Sierra Leone, Sri Lanka, Madagascar, Malaysia, Brazil, Indonesia, Thailand, Ukraine, and Vietnam. In Canada, some zircon is obtained from the processing of Athabasca tar sands. Undeveloped heavy mineral beach sand reserves containing zircon exist in New Jersey, the Carolinas, Georgia, Tennessee, Colorado, New Mexico, Oregon, Utah, Wyoming, Egypt, Malawi, Senegal, and Tanzania.

These heavy mineral sands deposits are mined to obtain the titanium minerals rutile, leucoxene, and ilmenite to supply the titanium metal and titanium oxide pigment industries. Depending on the deposit's composition and current market pricing, zircon and other minerals are viable byproducts. Australia and South Africa are major zircon exporters.

Mining of heavy mineral sands involves first removing a light sand overburden, followed by removal of the heavy sands layers using elevating scrapers and bulldozers, or by flooding the excavation and using dredges in the pond. The heavy minerals are concentrated by gravity separation, and the quartz, light minerals, fines, clay, and silt are returned to the back end of the excavation. Since the heavy mineral sands are only 4 – 7 % of the deposit, the site can be rehabilitated close to the original elevation, topsoil replaced, and native vegetation replanted. The concentrate is hauled to a ore-dressing site where the grains may be scrubbed to remove surface coatings, dried, and separated into individual mineral components: rutile, leucoxene, ilmenite, zircon, xenotime, monazite, staurolite, garnet, kyanite, and sillimanite. These separation steps utilize differences in the specific gravity, induced magnetism, and electrical conductivity of the individual minerals grains to gradually recover each mineral in good purity.

The various mining operations produce a range of zircon products from high grades with very low levels of impurities to lower grades where the impurities vary with the nature of the orebody and the type of separation process used. These various grades supply a range of applications: foundry sands, refractories, abrasives, opacifiers, zirconium chemicals, zirconium metal, and welding rod coatings. A typical analysis of zircon for the metal industry is 66.6 % $(Zr + Hf)O_2$, 0.2 % Al_2O_3, 0.15 % TiO_2, 0.1 % Fe_2O_3, 0.1 % P_2O_5, 0.025 % U, 0.020 % Th.

Baddeleyite [*12036-23-6*], ZrO_2, has been found in Brazil, South Africa, Sri Lanka, and Russia. Brazilian baddeleyite often occurs mixed with zircon. The mixture is known as caldasite and usually contains 65 – 80 % zirconium oxide. South African baddeleyite is a byprod-

uct of mining a volcanic orebody for copper and phosphate fertilizer. The baddeleyite concentrate contains 96 % zirconium oxide. Russian baddeleyite from the Kola Peninsula is a byproduct of open pit iron ore mining.

Eudialyte [*12173-26-1*], $(Ca, Na_2)_6(Zr, Fe)(Si_3O_9)_2(OH, Cl)_2$ has been found in Greenland, Norway, Brazil, Australia, Transvaal, and New Mexico. Some eudialytes contain 12 – 15 % zirconium oxide, yttrium, and small amounts of niobium and rare earth metals.

Hafnium Content. All known zirconium minerals contain hafnium, usually in the range of 1.5 – 2.5 % Hf/Zr + Hf, although higher hafnium contents have been found. There is a tendency for higher-hafnium ores to be also higher in uranium and thorium content. Hafnon, hafnium orthosilicate, with >95 % Hf/Zr + Hf was found associated with a tantalum ore in Mozambique.

1.4. Production

Processing steps for the production of zirconium metal from zircon sand are shown in Figure 1.

1.4.1. Ore Cracking

Zircon is a refractory mineral whose decomposition requires the use of high temperature and aggressive chemicals. Selection of a particular procedure depends on the subsequent product use or processing.

Caustic Fusion. Caustic fusion of zircon with a slight excess of sodium hydroxide at 650 °C (or sodium carbonate at 1000 °C) is the usual zircon decomposition process [8], [9]:

$$ZrSiO_4 + 4\,NaOH \rightarrow Na_2ZrO_3 + Na_2SiO_3 + 2\,H_2O$$

The cooled reaction mass is crushed and slurried in water. Water dissolves the sodium silicate and hydrolyzes the sodium zirconate to soluble sodium hydroxide and insoluble hydrous zirconia. The hydrous zirconia, recovered by filtration, can be fired to oxide, dissolved in mineral acid for further conversion to aqueous zirconium compounds, or dissolved in mineral acid for feeding to a hafnium extraction process.

A variant of the caustic fusion process uses less caustic to produce an acid-soluble sodium zirconium silicate

$$ZrSiO_4 + Na_2CO_3 \xrightarrow{1000\,^\circ C} Na_2ZrSiO_5 + CO_2$$

The frit from this reaction is added to strong acid to yield a solution containing sodium and zirconium salts and silica gel:

$$Na_2ZrSiO_5 + 4\,HCl \rightarrow 2\,NaCl + ZrOCl_2 + SiO_2 + 2\,H_2O$$

Chlorination. Fluidized-bed carbochlorination of milled zircon sand is the zircon decomposition process used by American and French zirconium metal producers. Chlorine is the fluidizing gas. The reaction is endothermic and supplemental energy is supplied, usually by induction heating of the interior graphite wall of the chlorinator.

$$ZrSiO_4 + 4\,C + 4\,Cl_2 \xrightarrow{1100\,^\circ C} ZrCl_4 + SiCl_4 + 4\,CO$$

The product gases are cooled to 200 °C in a primary condenser that collects zirconium (and hafnium) tetrachloride as a powder. The remaining gas mixture is cooled to −20 °C in a secondary condenser, collecting silicon tetrachloride as a liquid which is subsequently purified and used to make fumed silica, fused quartz, and fused-quartz optical fiber.

Thermal Dissociation. Thermal dissociation of zircon in an arc plasma forms zirconium oxide in droplets of liquid silica. Rapid quenching, to minimize recombination, produces intimately mixed crystals of zirconium oxide in a bead of amorphous silicon oxide [10].

$$ZrSiO_4 \xrightarrow{1800\,^\circ C} \text{liquid} \xrightarrow{\text{Quench}} ZrO_2 + SiO_2$$

The mixture can be leached with sulfuric acid to yield a zirconium sulfate solution and insoluble silica, or leached with sodium hydroxide to yield a sodium silicate solution and insoluble zirconium oxide.

Fluorosilicate Fusion. The fusion of zircon and potassium hexafluorosilicate produces potassium hexafluorozirconate [11].

$$ZrSiO_4 + K_2SiF_6 \xrightarrow{700\,^\circ C} K_2ZrF_6 + 2\,SiO_2$$

Figure 1. Flow diagram for production of zirconium

The fused mass is crushed, then the fluoride salt is dissolved with acidified hot water. The hot solution is filtered to remove silica and cooled to crystallize potassium hexafluorozirconate.

Lime Fusion. Fusion of zircon with limestone or dolomite produces calcium zirconate and calcium or magnesium silicate:

$$2\,ZrSiO_4 + 5\,CaCO_3 \rightarrow 2\,CaZrO_3 + (CaO)_3(SiO_2)_2 + CO_2$$

On cooling, the fused mass disintegrates into a very fine calcium silicate powder and coarse calcium zirconate crystals, which can be recovered by mechanical means. The acid-soluble calcium zirconate can be converted into zirconium salts or zirconium oxide.

Carbiding. An intimate mix of zircon sand and coke is continually fed into an open-top electric arc furnace. Insufficient carbon is used for complete conversion to carbide, so that silicon monoxide is vaporized at the arc temperature [12]:

$$ZrSiO_4 + 3\,C \xrightarrow{2500\,^\circ C} Zr(C,N,O) + SiO + 3\,CO$$

A crude zirconium carbonitride ingot grows under the electrode, surrounded by unreacted mix, which acts as insulation for the steel furnace shell. When the furnace is full, it is moved to a cooling location. When cool, the ingot is separated from unreacted charge, which is recycled. The product is a dense block, having a silver to golden-yellow fracture surface, depending on nitrogen content. The block is broken and crushed to −75 mm chunks, which are subsequently chlorinated to zirconium tetrachloride. If the hot ingot is immediately removed from the furnace shell and unreacted charge, the ingot is oxidized to zirconium oxide containing ca. 5 % silica.

High-Temperature Fusion. Direct electric arc smelting of baddeleyite or zircon is used to make fused zirconia or fused alumina – zirconia – silica (AZS). The silica is partially vaporized and recovered as fumed silica.

Baddeleyite is converted to zirconium sulfate by direct dissolution in concentrated sulfuric acid at ca. 200 °C. The recovery is low. Better recoveries are obtained by first heating the baddeleyite with lime to yield calcium zirconate, which reacts with sulfuric acid to give zirconium sulfate and gypsum.

1.4.2. Hafnium Separation

Zirconium and hafnium are very similar chemically and metallurgically, and for most uses of zirconium their separation is unnecessary. Their separation is conducted only to produce hafnium-free zirconium metal for the nuclear power industry. Of the many methods developed since the discovery of hafnium, four are used industrially: fluoride salt crystallization, methyl isobutyl ketone extraction, tributyl phosphate extraction, and extractive distillation, in order of their development. In addition, ion exchange has been used for low-throughput, low-investment operations.

Fluoride Salt Crystallization. The first separation of zirconium and hafnium by repeated crystallization of potassium hexafluorozirconate from hot aqueous solution is credited to Von Hevesy [13]. The solution is acidified to minimize oxide – fluoride salt formation. At each step the salt crystals are depleted in hafnium. This multistep recrystallization procedure has been used for many years in the Ukraine [14].

Methyl isobutyl ketone extraction, developed at Oak Ridge National Laboratory and used by both American producers, is based on the preferred extraction of a hafnium dihydroxide thiocyanate complex from hydrochloric acid solution by methyl isobutyl ketone [15].

Zirconium – hafnium tetrachloride, produced by carbochlorination of zircon, is dissolved in water, with hydrolysis to form zirconium – hafnium dihydroxide chloride in a hydrochloric acid solution. This solution is contacted with methyl isobutyl ketone to extract iron as $HFeCl_4$ into the organic solvent. Then ammonium thiocyanate is added to the dihydroxide chloride solution, providing a mixed dihydroxide chloride/dihydroxide thiocyanate solution of zirconium and hafnium. This solution is countercurrently contacted with a methyl isobutyl ketone/thiocyanic acid solution to preferentially extract hafnium dihydroxide thiocyanate into the organic phase. This is conducted in a series of mixer-settlers or a series of packed or internally agitated columns. Hafnium is recovered from the ketone solution by scrubbing with dilute sulfuric acid.

Zirconium is recovered from the hydrochloric acid solution by heating the solution above 90 °C, adding precisely two moles of sulfuric acid to each five moles of zirconium, and then carefully raising the pH to 1.2 – 1.5 with dilute ammonium hydroxide. This precipitates a granular zirconium basic sulfate, $Zr_5O_8(SO_4)_2 \cdot x\,H_2O$ which is easily filtered and washed to remove aluminum and uranium impurities. The sulfate filter cake is repulped with dilute ammonium hydroxide to convert it to zirconium

hydrous oxide, which is fired to give pure zirconium oxide [16].

In this extraction process, methyl isobutyl ketone and thiocyanate are recovered and reused, but considerable quantities of hydrochloric acid, sulfuric acid, and ammonia are consumed. Zirconium produced typically contains 35 – 90 mg Hf/kg and the hafnium contains 200 – 2000 mg Zr/kg, but any degree of separation can be attained, without further chemical consumption, by providing fewer or more contacting stages during separation.

The zirconium oxide and hafnium oxide are each chlorinated in fluidized beds to give their tetrachlorides. Chlorination of the oxides is faster than that of the silicates, and can be efficiently conducted at a lower temperature.

$$ZrO_2 + C + 2\,Cl_2 \xrightarrow{900\,^\circ C} ZrCl_4 + CO_2$$

The zirconium tetrachloride is then purified by sublimation at 350 – 400 °C in a nitrogen atmosphere containing 1 – 5 % hydrogen. The hot gases pass through a filter to remove entrained particles before being cooled to condense the zirconium tetrachloride. This sublimation reduces the levels of oxide, iron, phosphorus, and aluminum.

Tributyl phosphate extraction, developed concurrently in Britain, France, and the United States, was used commercially in the United States and is being used in India to obtain zirconium for the nuclear industry [17]. Hydrous zirconium – hafnium oxide from caustic fusion of zircon is dissolved in nitric acid. The nitric acid solution is countercurrently contacted with an organic solution of tributyl phosphate in kerosine. A zirconium tributyl phosphate complex is preferentially extracted into the kerosine, leaving hafnium and most metallic impurities in the aqueous phase. The zirconium is stripped from the kerosine solution with dilute sulfuric acid solution, precipitated, and fired to pure zirconium oxide.

Extractive Distillation. Hafnium tetrachloride is slightly more volatile than zirconium tetrachloride, and separation by fractional distillation would be feasible if the tetrachlorides could be handled as liquids. However, the tetrachlorides are either solid or gaseous, depending on temperature, unless kept under pressure while being heated to the triple point of zirconium tetrachloride (435 °C, 2.0 MPa). However a distillation process was developed in which the liquid phase was molten potassium chloroaluminate, in which zirconium and hafnium tetrachloride are soluble without forming compounds that could impede the separation or the recovery of separated chloride [18].

The zirconium – hafnium tetrachloride from carbochlorination of zircon is first purified by sublimation. The purified tetrachloride is revaporized and the vapor is introduced into the distillation column, above the midpoint. The potassium chloroaluminate liquid, equilibrated with hafnium-rich tetrachloride, is fed into the top tray of the distillation column, which is at 350 °C. As the liquid cascades down the column, it is gradually stripped of the more volatile hafnium tetrachloride while acquiring zirconium tetrachloride from the rising vapor. The zirconium tetrachloride in the liquid melt reaching the bottom of the column contains <50 mg Hf/kg Zr.

In the boiler at the column bottom some of the zirconium tetrachloride is vaporized to provide the rising vapor in the column. From the boiler the liquid melt goes to a short, hotter column where it is stripped with nitrogen to remove the product zirconium tetrachloride.

The stripped liquid melt is returned to an absorber – condenser above the distillation column where it is equilibrated with hafnium-rich tetrachloride vapor, then returned to the top of the distillation column. Unabsorbed hafnium-rich tetrachloride vapor ($HfCl_4$ content 30 – 50 %) is led to a condenser. The hafnium-rich tetrachloride is accumulated until it can be reprocessed in the distillation column in a separate campaign to recover pure hafnium tetrachloride (<1 % $ZrCl_4$).

Control of the potassium to aluminum ratio in the melt is crucial. Excess potassium chloride preferentially bonds with hafnium tetrachloride, reducing its effective vapor pressure and thereby decreasing the separation efficiency. With a deficiency of potassium chloride, aluminum chloride is lost into the nitrogen stream in the stripper, contaminating the zirconium tetrachloride product.

This extractive distillation process has a higher yield than the liquid – liquid extraction

processes, does not consume large quantities of chemicals, and eliminates the rechlorination step. It is very capital intensive.

Other Processes. Although zirconium is not easily reduced except by very strong reducing agents, it can be reduced more easily than hafnium. This has led to several separation procedures. The most significant [19] involved both molten metal (zinc base) and molten halide salts for good contact between the phases and for the close approach to equilibrium needed for good separation factors.

1.4.3. Reduction to Metal

Oxygen strengthens zirconium metal, decreasing its ductility and therefore its formability as a metal. To produce ductile zirconium metal, the zirconium compound to be reduced and the reducing agent should be as free of oxygen (and nitrogen and carbon) as possible. Anhydrous zirconium tetrachloride or tetrafluoride are usually used.

Kroll Process. Ductile zirconium metal is produced by reduction of pure zirconium tetrachloride with molten magnesium under an inert gas (helium or argon). The reduction retort is a long, vertical cylinder composed of two sections. The lower third is a stainless-steel-lined crucible which holds the magnesium ingots. The upper two-thirds has a central annular pipe slightly shorter than the retort wall. The space between the wall and the central pipe is filled with zirconium tetrachloride powder, then the two sections are welded together and a lid is bolted to the top. The assembled retort is warmed to 200 °C, evacuated and filled with argon several times to remove the last traces of air. The retort is lowered into a furnace with heating zones for each retort section. The lower section is then heated to 850 °C to melt the magnesium, and argon is bled from the warming retort to maintain atmospheric pressure (the retort is not a pressure vessel). Zirconium tetrachloride vapor passes down through the central pipe, which communicates with the lower section, and is reduced by the molten magnesium. At the end of the reduction, the lower crucible contains a thick suspension, or mud, of tiny zirconium metal beads in liquid magnesium, under a layer of liquid magnesium chloride. The retort is cooled and unloaded. The stainless steel liner is separated from the reduction mass and the layer of magnesium chloride is mechanically removed from the zirconium – magnesium metallic regulus. Several reduction reguli are stacked and loaded into a distillation furnace for removal of magnesium and residual magnesium chloride. The distillation is conducted in a vacuum (<1 Pa), with the charge located in the upper end of the retort. The bell furnace around the top of the retort is heated in programmed steps, reaching 980 °C in ca. 30 h. As the charge heats, the magnesium chloride melts and drains away, and the magnesium metal slowly evaporates, condensing on the water-cooled retort wall. As the magnesium evaporates, the zirconium beads come into closer contact and begin to sinter together. The final sintered porous mass is known as zirconium sponge. The heating schedule is critical: If the magnesium receives heat faster than heat is removed by magnesium transpiration at the surface of the reguli, the reguli become soft and flow down out of the heated zone. After the retort is cooled and the sponge conditioned by slow, controlled exposure to air, the sponge regulus is removed from the retort. The regulus is broken into chunks by using a hydraulic chisel. The chunks are sorted into quality grades depending on color and relative location in the regulus. The chunks are crushed to less than 2 cm, and screened to remove -20 mesh fines, which are higher in impurities.

Other Reduction Processes. Ductile zirconium has been produced commercially in a two-step sodium reduction analogous to a titanium reduction process [20]. Zirconium tetrachloride vapor and liquid sodium are both slowly fed into an argon-filled stirred reactor containing granular sodium chloride to obtain a $ZrCl_2 - NaCl$ mixture. This first step is very exothermic and the feed rate is controlled to allow excess heat to escape. The mixture is then transferred to a reactor by means of a screw conveyor. The reactor, already loaded with sodium, is sealed and heated to 800 °C:

$$ZrCl_2 + 2\,Na \rightarrow Zr + 2\,NaCl$$

The cooled mass was mechanically broken out of the reactor and leached with water to remove the sodium chloride from the zirconium. However, it was necessary to drip-melt the zirconium, forming splat-cooled chunklets, to remove the last traces of salt.

The Russian practice is to reduce potassium hexafluorozirconate with calcium metal in a sealed bomb. In Canada, zirconium tetrafluoride was reduced with calcium metal in a sealed bomb.

Zirconium oxide can be reduced by calcium or magnesium. Finely divided metal powder is recovered by leaching with cold hydrochloric acid. The powder has 0.3 – 0.5 % oxygen, and would not be ductile or melleable if melted into ingot. The powder particles are 1 – 8 µm in diameter and are very pyrophoric.

Electrolysis. Electrowinning and electrorefining of zirconium have been conducted but are not in commercial use. A pilot electrolysis system tested for zirconium was used commercially for hafnium [21]. A summary of the difficulties in developing an electrolysis process is given in [22].

1.4.4. Refining

From 1925 to 1945 the van Arkel and de Boer iodide process was the only consistent method for obtaining pure ductile zirconium metal. Now Kroll zirconium is used for most applications and iodide zirconium is used only when the highest purity is needed. In the iodide process, iodine vapor is reacted with Kroll zirconium sponge or calcium-reduced zirconium metal powder to produce zirconium tetraiodide [23], [24]. The tetraiodide vapor diffuses to a heated filament, usually zirconium wire, where the iodide is thermally dissociated, depositing zirconium and releasing iodine to repeat the cycle:

$$2\,I_2 + Zr \xrightarrow{300\,^\circ C} ZrI_4 \xrightarrow{1400\,^\circ C} Zr + 2\,I_2$$

The reaction is conducted in an Inconel vessel at an absolute pressure of 40 Pa. The wire filament diameter grows as zirconium is deposited on the wire. Bars up to 40 – 50 mm in diameter can be grown.

Electron beam melting is not usually used to purify zirconium because the metal's vapor pressure at its melting point is higher than that of most impurities. Iron and aluminum levels can be reduced by electron beam melting. The metal vapor pressure results in considerable evaporation loss in the high vacuum utilized in electron beam melting.

1.5. Fabrication

The procedures for melting zirconium sponge and for conversion of ingots to mill products are similar to those developed by the titanium industry, with the added requirement that high-neutron-cross-section materials such as boron be rigorously excluded.

Melting. Zirconium sponge is pressed into compacts, cylindrical or hexagonal discs, which then are stacked and surface-welded together in an electron beam furnace to form an electrode. The discs may be pure sponge, or may contain alloying ingredients added in the midst of each disc during pressing, or may be recycled clean turnings of the same intended composition. The welded electrode is then melted in a vacuum arc furnace. An electric arc is struck between the electrode and a starter pad of zirconium chips in the bottom of a water-cooled cylindrical copper crucible. The electrode is not cooled and it slowly melts off in the arc, producing a molten pool in the cooled copper crucible. The pool edge freezes on contact with the cool crucible wall so that the remaining pool is separated from the crucible wall. As melting continues, the electrode is consumed and the ingot grows in the crucible, cooling and solidifying from the bottom and sides as the pool moves upward. The outer skin contains impurities that vaporize during melting, primarily magnesium and magnesium chloride, and any possible copper pickup from sliding the ingot out of the crucible. The first-melt ingot is surface machined to remove the outer skin. Since the molten pool was, at any one instant, only a small portion of the ingot, distribution of alloying ingredients in the ingot is not homogeneous after one melt. Two machined first-melt ingots are formed into a second electrode, first-melt bottom now at the top, which

is again melted in a larger diameter copper crucible. A third melt assures complete homogeneity and dissolution of any inclusions. 750 mm diameter ingots of up to 9 t are produced.

Forming. Ingots are surface machined then heated to over 1000 °C and hot forged to 50 – 150 mm thick slabs, or to 200 – 400 mm diameter rounds. At the conclusion of hot working, the surface oxide scale is removed by sandblasting and abrasive-wheel grinding. The underlying dark layer of oxygen-diffused metal is removed by pickling in dilute hydrofluoric – nitric acid solution [25].

Strip and sheet are formed by cold working the slabs in conventional rolling mills, including producing foil in a Sendzimir mill. The allowable cold deformation before annealing is 20 – 70 %, depending on alloy toughness and the type of deformation process. Intermediate and final anneals are conducted in vacuum or inert-atmosphere furnaces.

For round products, the 200 – 400 mm rounds are cut to length, hot rotary forged to bar, cleaned, and swaged or drawn to rod or wire for welding use.

For hollow round products, short lengths of the rounds are drilled or trepanned to produce extrusion billets which are warm extruded to heavy wall tubeshells. Prior to extrusion the billets are coated with proprietary layers of glass, graphite, or copper. These coatings minimize oxidation of the surface and function as a lubricant during extrusion, but must be removed before subsequent cold working.

The extruded tubeshells are tube-reduced in pilger mills, with intermediate vacuum anneals, to produce thin-wall tube lengths. Zircaloy 2 or 4 (see Section 1.9) tubes are used as cladding for uranium oxide pellets for light-water nuclear fuel assemblies. This is the major use of zirconium metal.

Powder Metallurgy. Malleable zirconium and high-zirconium alloy powders are obtained by the hydride – dehydride process. Zirconium is hydrided by heating to 800 °C and cooling in a pure hydrogen atmosphere. The product is brittle and easily ground to powder in an argon atmosphere chamber. The hydrogen is then removed by degassing in a vacuum above 650 °C. The metal powder is screened to obtain the desired particle-size distribution. The hydride powder can also be directly pressed and sintered, allowing for hydrogen outgassing.

Welding. Zirconium can be welded in argon or helium atmospheres. If welding is not conducted in an inert-gas chamber, the welding fixtures or jigs must be so arranged that argon or helium gas flooding is sufficient to keep air completely away from the welding zone. Care must be taken to avoid oxygen or hydrogen pickup as these affect the ductility and corrosion behavior of the heat-affected zone. Electron beam welding is used for high-quality welds in repetitive situations such as nuclear fuel assembly.

While zirconium can be welded to titanium, hafnium, niobium or tantalum, joining of zirconium with other metals (i.e., copper, iron, nickel) by fusion welding is not practical because of the formation of brittle intermetallic phases. To join these metals, methods must be used that avoid formation of liquid phases but use mechanical interlocking: friction welding or explosive bonding, which is used for cladding of zirconium lining onto ferrous alloys. Welding of zirconium to titanium, niobium, or tantalum destroys the corrosion resistance.

1.6. Hazards in Handling Zirconium Metal

Solid zirconium is not hazardous, but any high-surface-area form of zirconium metal (powder, dust, chips, foil, sponge) is hazardous because of its easy ignition in air and its exothermic reaction with many other elements and compounds.

Zirconium chemical equipment, if used under conditions not recommended, such as sulfuric acid above 80 % concentration or strong hydrochloric acid with ferric ion contamination, may suffer intergranular attack. This creates a highly pyrophoric surface layer, usually black, that is ignited easily when dry. The combination of γ-zirconium hydride and metallic particles has been suggested to be responsible for the pyrophoricity. Careful treatment in hot air or steam is recommended to stabilize this surface [26].

The ignition temperature of zirconium powder varies with particle size, method of production, and prior treatment. A <40 mm pow-

der prepared in inert atmosphere will immediately ignite upon exposure to air, unless it is first slowly exposed such as by gradually back-filling the airlock of a glove box, allowing the heat of surface oxidation to dissipate.

Zirconium powder produced wet, such as by acid leaching of a reduction mass, is usually safe if the water content is >50 wt %. This prevents localized temperature excursions. The powder should not be allowed to settle and compact for long periods of time, especially when freshly prepared. Hydrogen is still slowly generated, and accumulated gas bubbles in a compact powder mass can insulate some grains from the water, allowing localized heating to ignition.

Drying of wet powder is most hazardous. While wet powder is harder to ignite than dry powder, it burns much more vigorously because of the available oxygen from the water and is more explosive because of the generation of hydrogen and steam. The most hazardous water content is 5 – 10 %. Powder is dried as a thin layer on warm-water-heated trays in a vacuum drier.

Machining of zirconium generates fine chips which can be ignited easily. Hot chips are the usual ignition source. The best metal removal procedures consistent with keeping chip temperatures down are: using slow cutting speeds with heavy feeds, and using an ample flood of water-soluble cutting oil as a coolant. Accumulation of chips should be avoided. Chips should be removed as generated and stored in water-filled drums kept outside in an isolated area. Coarse chips, if not contaminated, possibly may be chopped, cleaned, and recycled. Fine chips should be disposed of by burning in an incinerator or an open pit, feeding the fire in small increments of 1 – 2 kg.

Many unexpected flash fires have been caused by improper handling of machining chips resulting in more than one incident of fatal flash burns. Workers involved in handling, storing, cleaning, or disposal of machining chips or other zirconium fines should wear heat-reflectant clothing.

Zirconium fires can be controlled only by cutting off the supply of oxygen and other oxidants such as water, carbon dioxide, carbon tetrachloride, iron oxide, and limestone. Small fires can be smothered with dry silica sand or dry table salt, or with argon or helium if the zirconium is enclosed in a container. Do not use water. Large fires are best left alone and allowed to burn out, keeping the surroundings from igniting.

Safe handling procedures for zirconium, including machining, grinding, welding, and descaling, are discussed in [27].

Solutions that corrode zirconium metal may react violently or explosively with zirconium powder. A solution of 83 % concentrated H_2SO_4 and 17 % $KHSO_4$ was added dropwise to 2 g of zirconium powder. Upon adding about 2 mL of the acid mixture, a violent explosion occurred.

1.7. Grades and Specifications

There are two parallel grading systems for zirconium: industrial (intended primarily for use as a construction material for equipment and piping in the chemical industry) and nuclear (intended for use as a construction material for fuel cladding and internal parts for nuclear power reactors). Some of these grades have little present usage.

The industrial grades are listed,showing first the ASTM designation, then any alternative designation:

R 60 701 (Zr 701)	an unalloyed zirconium of low hardness and containing low levels of the impurities iron and chromium
R 60 702 (Zr 702)	the usual unalloyed zirconium specified for general corrosion-resistant service
R 60 703 (Zr 703)	the least pure, available only as sponge metal, used primarily for alloying with other metals
R 60 704 (Zr 704)	an alloy containing tin and iron and used in chemical process applications where the higher strength of the alloy is needed and the corrosion resistance is sufficient
R 60 705 (Zr 705)	an alloy containing 2.5 % niobium used where high strength is needed
R 60 706 (Zr 706)	a softer version of Zr 705 used specifically for severe forming applications

All of these grades may contain the usual 2 % hafnium, or may be furnished hafnium-free. This does not affect the quality or usefulness in industrial applications.

Zirconium for use in nuclear service is supplied to meet individual company specifications (which usually use ASTM nuclear grades and specifications as a starting point). The nuclear grades are listed, showing first the ASTM designation, then any alternative designation:

R 60 001	unalloyed zirconium with a long list of controlled impurities to make it satisfactory for nuclear service. Primarily iodide zirconium for the first reactor core
R 60 802	(Zircaloy 2) an alloy containing 1.5 Sn, 0.15 Fe, 0.1 Cr, and 0.05 Ni used primarily in pressurized water reactors
R 60 804	(Zircaloy 4) an alloy containing 1.5 Sn, 0.2 Fe, 0.1 Cr used primarily in boiling water reactors
R 60 901	(Zr 2.5 Nb, 705) an alloy containing 2.5 Nb, used primarily for pressure tubes in the Canadian CANDU reactors

All of these grades are hafnium free, i.e., <100 mg Hf/kg Zr.

U.S. and Canadian specifications for zirconium products are listed in Table 3.

1.8. Uses

Zirconium is produced almost exclusively as the hafnium-free metal. Most of this metal is used in zirconium alloys containing low levels of tin or niobium, for structural parts in the core of water-moderated nuclear reactors. For this use, zirconium has several desirable attributes: it is ductile, i.e., it can be formed. It has good strength up to 450 °C, i.e., it does not deform at reactor core temperature. Its alloys have hotwater and steam corrosion resistance, i.e., it lasts a long time in normal use. It has low thermal neutron cross section, i.e., neutrons are not absorbed, shutting down the nuclear reaction. Its ore is readily available.

Zirconium is used for building chemical process equipment for those applications where its corrosion resistance is needed. In hot sulfuric acid up to 65 % concentration, zirconium is used in facilities which produce hydrogen peroxide, acrylic films and fiber, methyl methacrylate, and butyl alcohol. Zirconium is used in the cooler condenser on a nitric acid absorption column. The operation conditions are 200 °C and 1035 MPa. One condenser constructed with zirconium tubes and zirconium/304 L stainless steel explosion-bonded tubesheets contains over 18 km of zirconium tubing and has been in service since the mid 1970s. Zirconium is used in contact with ammonium carbamate in urea production, in production of acetic and formic acid, and in many hydrochloric acid environments. In these applications zirconium's corrosion resistance is excellent and the long life of the equipment has justified the use of zirconium.

Zirconium foil, 0.002 mm, is used as the ignition-flash material in photographic flash bulbs, just as zirconium powder used to be one ingredient in the old open "flash pans" of earlier photographers, but this usage is fading because of builtin electronic flashes in newer camers. Zirconium powder is still used in pyrophoric applications.

Zirconium and zirconium alloys with aluminum, iron, titanium, or vanadium are used for gettering in vacuum tubes [28], inert gases, and ultra-high-purity environments for the semiconductor industry [29]. Heated zirconium absorbs, traces of oxygen, nitrogen, carbon monoxide, carbon dioxide, and water irreversibly. Hydrogen is reversibly adsorbed. The adsorbed materials diffuse into the bulk of the getter alloy, providing fresh surface for renewed adsorption. For ultra-pure inert gases, getters are used at the point of use to remove contaminants picked up from storage tanks or piping systems. Getters are used in gettering pumps for improving the quality of vacuum in ultra-high-vacuum systems.

Zirconium in the forms of clean, chopped machining chips, crushed sponge or magnesium-zirconium reguli turnings are often used in place of master alloys for zirconium additions to steel melts, super alloys, and nonferrous alloys.

1.9. Economic Aspects

Ores and Minerals. The four major producing countries for the world's current estimated annual production of 10^6 t of zirconium minerals are Australia 50 %, Republic of South Africa 25 %, United States 10 %, and the Ukraine 6 %. Australia and South Africa are the major exporting countries. Europe, Japan, China and the United States are major importers.

There are no zircon mines. Zircon is recovered as a byproduct of the extraction of the titanium-containing minerals rutile, ilmenite, and leucoxene. The producers of these minerals adjust their output to follow paint-market demand for titanium oxide pigment. Therefore, the supply and the demand for zircon are rarely

Table 3. Specifications for zirconium and zirconium alloy products

in phase and zircon prices have wide swings. During 1975 – 1995, zircon prices ranged from $ 83 per tonne to over $ 1100 per tonne in late 1989. The price during 1990 – 1995 averaged $ 275 – 330 per tonne, varying with quality.

Consumption of zirconium ores continues its gradual growth. In 1975, world production of zircon was 455 000 t and by 1995 it had essentially doubled. Currently, the growth in demand for zirconium materials is being led by its use as a opacifier in glazed ceramic tile manufacture.

Metals. Less than 4 % of the zirconium ores are used in the manufacture of zirconium metals. Since the incident at Three Mile Island, the meltdown at Chernobyl, and the ending of the cold war, the demand for commercial nuclear power and for military naval propulsion systems has diminished. It is estimated that in 1994 total world production was ca. 3600 t, compared to ca. 7300 t in 1982.

The United States has the largest production capacity with two producers: Teledyne Wah Chang in Albany, Oregon (nameplate capacity ca. 2700 t/a) and Western Zirconium in Ogden, Utah (nameplate capacity ca. 1360 t/a). In France, Compagnie Europeene du Zirconium (CEZUS), owned jointly by Pechiney, Framatome and Cogema, has a capacity of ca. 1800 t/a. The capacity of the Prinieprovsky plant in the Ukraine is estimated to be 2700 t/a of calcium-reduced reguli, which is crystal-bar refined at Glasnov, Russia. The Indian plant in Hyderabad has a nameplate capacity of 270 t; production is consumed internally. Japan is not presently producing zirconium sponge.

Prices in 1994 were $ 20 – 28 per kilogram of sponge and $ 45 – 110 per kilogram for cold-rolled sheet, strip, or foil.

2. Zirconium Compounds

In anhydrous halide-salt melts zirconium may exhibit valences of 4, 3, 2 or 1, but in aqueous solution its oxidation state is +4. Zirconium compounds have coordination numbers of 6, 7, or 8. The colorless ion is hydrolyzed in aqueous solution. Because of the ion's high charge and small radius, zirconium has a great tendency to hydrolyze and to form polymers. It is believed that most zirconium in aqueous solution is present as a tetramer $[Zr_4(OH)_4]^{8+}$ [30]. Therefore, $ZrOCl_2 \cdot 8\,H_2O$, by formula, is actually $[Zr_4(OH)_4 \cdot 7\,H_2O]_4Cl_8$. Hydrolysis and further polymerization of these tetramer units occurs with time, by heating, or with decreasing acidity. True equilibrium may take days or weeks. The following anions are listed with respect to their ability to form complexes with zirconium: $I^- \approx Br < ClO_4^- < Cl^- < NO_3^- < SO_4^- < F^- \approx C_2O_4^{2-} \approx PO_4^{3-} < CO_3^{2-} < OH^-$.

2.1. Zirconium Silicate

Zirconium silicate, $ZrSiO_4$, occurs in nature as the mineral zircon. It can be made by heating an intimate mix of zirconia and silica to just above 1500 °C. The crystals are tetragonal with the zirconia and silica linked through shared oxygen atoms, forming edge-sharing alternating ZrO_8 triangular dodecahedra and SiO_4 tetrahedra [31]. Other, more complex silicates are also found in nature (see Section 1.5). Zirconium silicate is resistant to acids, aqua regia and cold alkali solutions. It is readily attacked by sodium oxide, by sodium hydroxide at 600 °C, and by reaction with hot alkaline compounds (see Section 1.4.1). Above 800 °C zircon is reduced by carbon, the basis for the carbochlorination process.

Uses. Zircon's mechanical strength, chemical stability and high melting point make it a desirable refractory. Total world production of zircon was $(770-960)\times10^3$ t/a for 1990 – 1995. Of this ca. 35 – 40 % is used in ceramic glazes and enamels, ca. 30 – 35 % in refractories, 15 – 20 % in foundry use, 8 – 12 % in abrasives, and 8 – 12 % in other uses including chemicals, metals and alloys, and glass constituents.

In the largest use, decorative ceramics, milled or micronized zircon is used as an opacifier for tile glazes and porcelain enamels. Zircon's high refractive index gives the glaze a white, opaque appearance.

Zircon is a popular refractory in the glass and steel industries. The glass industry uses fused zircon and AZS (alumina – zirconia – silica) refractories (→Refractory Ceramics, Chap. 7.1.4.) which have a high corrosion resistance to molten glass. The AZS refractories are made by electric furnace fusion of alumina and zircon. The steel industry uses zircon in ladles and continuous casting nozzles. Refractory applications were once the leading markets for zircon but they decreased significantly following the zircon shortage in the late 1980s. Other less-expensive refractories such as alumina spinels were substituted.

Zircon is used in foundries as a basic mold material and as a facing on other mold materials. The high thermal conductivity of zircon gives higher cooling rates than other mold materials. Zircon's high melting point, low coefficient of thermal expansion, and chemical stability make it the preferred mold facing, particularly in precision casting.

Alloyed AZ (alumina – zirconia) abrasives (→Abrasives, Chap. 3.2.) are made from 60 – 90 % alumina – zirconia grains produced by fusing alumina with baddeleyite, or zirconia derived from zircon, in electric arc furnaces. The addition of zirconia toughens the alumina, reducing its brittleness. The abrasives have particular application in the grinding of steel and steel alloys because of high strength, hardness, and surface crystal sharpness, resulting in fast grinding and long wheel life.

Zircon is added to glass for television tubes because of its X-ray absorption properties and its ability to toughen the glass.

2.2. Zirconium Oxide

Zirconium oxide [*1314-23-4*] occurs naturally as the mineral baddeleyite and is produced by calcining of other zirconium compounds. Three phases are stable at atmospheric pressure: cubic above 2370 °C, tetragonal above 1170 °C, and monoclinic below 1000 °C. Transformation of the monoclinic phase to the tetragonal phase begins at ca. 1050 °C and is complete at ca. 1170 °C. The transformation is accompanied by a volume shrinkage of 3 – 5 %. The transformation has a thermal hysteresis: on gradual cooling the tetragonal phase is stable to ca. 1000 °C and only finishes conversion to monoclinic at ca. 800 °C. With rapid quenching the tetragonal phase is metastable to room temperature.

The high-temperature cubic phases can be stabilized down to room temperature by the addition of magnesia, calcia, yttria, or rare earth oxides, whose presence creates vacancies in the zirconium anion lattice. These stabilized zirconium oxides contain from 3 % yttria to 8 % calcia. They have the same crystal structure from room temperature to melting, avoiding the catastrophic mechanical failure suffered by pure zirconia ceramic parts on transforming from the tetragonal to monoclinic phase while cooling.

Later, Garvie [32] discovered that certain partially stabilized zirconias could be thermally cycled to precipitate metastable tetragonal zirconia within the grains of cubic zirconia. These

materials had higher toughness than fully stabilized zirconias. The increased toughness of partially stabilized zirconia (PSZ) is the result of stress-induced martensitic transformation of the metastable tetragonal grains to the monoclinic form in the stress field of a propagating crack. This led to development of an entirely tetragonal zirconia, known as tetragonal zirconia polycrystal (TZP). The evolution of these materials and their growing application in structural ceramics can be followed in [33–38]. An introduction to zirconia ceramics is given in [39].

Zirconia also has a high-pressure (10 GPa) orthorhombic structure which can be stabilized to atmospheric pressure by addition of >12 mol % of niobia or tantala or a mixture thereof [40]. No transformation toughening was found [41].

Stable lower oxides of zirconium are not known, although oxygen dissolved in the zirconium metal lattice has led to the identification of some superstructures as $ZrO_{0.3}$ [42]. Zirconium monoxide, ZrO, has been observed in mass spectrographic measurements [43]. The black oxide surface on zirconium metal after exposure to water at 350 °C is a slightly substoichiometric $ZrO_{1.95}$.

Zirconia is very resistant to acids and alkalis, but slowly dissolves in concentrated hydrofluoric acid or hot concentrated sulfuric acid. Zirconia is resistant to many fluxes, molten glasses, or melts, silicate, phosphate, or borate, but is attacked by fluoride or alkaline melts. Zirconium oxide and alkaline oxides or caustics can be fired together to form solid-solution oxides, zirconate compounds, or a mixture of both.

Zirconium oxide is reduced by carbon, beginning at ca. 600 °C. With excess carbon, in a vacuum furnace, the reaction proceeds rapidly to zirconium carbide at 1500 °C. In the presence of chlorine the carbon reduction gives zirconium tetrachloride and carbon dioxide.

Uses. Zirconium oxide is used to coat the surface of titanium oxide pigment particles for some grades of exterior service paints. The coating minimizes ultraviolet excitation of the titania, which would interact with the organic paint binder, shortening the service life. Zirconia has been used in place of titania as the pigment of white camouflage paints for use in snow environments because zirconia more closely simulates snow in the infrared and microwave spectra. Over 300 t of single-crystal cubic zirconia are grown each year to provide low-cost gems for the jewelry trade [44]. Stabilized zirconia is being used in everyday applications such as fishing rod ferrules, knives, unbreakable shirt buttons, and golf putter heads.

While stabilized zirconias are insulators at room temperature, at elevated temperatures the vacancies in the anion lattice allow O^{2-} ions to diffuse and the zirconia becomes a solid electrolyte with applications in oxygen sensors and high-temerature fuel cells. Some stabilized zirconias can be used as resistors or susceptors. Inductively heated yttria-stabilized zirconia cylinders are used as heat sources to melt quartz boules for the drawing of quartz optical fibres.

Zirconia is a constituent of lead zirconate titanate (PZT) used in piezoelectric ceramics (→Ceramics, Electronic) for applications as gas furnace and barbeque igniters, microphone and phonograph crystals, ultrasonic transducers for medical ultrasound imaging, for agitation in cleaning tanks, and for underwater sonar. With the further addition of lanthanum (PLZT), ferroelectric optically active transparent ceramics have become available (→Ceramics, Electronic) [45].

2.3. Hydrous Zirconium Oxide

Neutralization of an aqueous zirconium solution causes hydrolysis and condensation of the zirconium cations, forming a white gel called zirconium hydroxide but generally considered to be a hydrous oxide. The freshly precipitated amorphous gel is generally considered to be a network of tetramer units $[Zr_4(OH)_8 \cdot 16\,H_2O]^{8+}$ linked through hydroxyl groups; it is easily dissolved by dilute or weak acids. As the gel ages some of the hydroxyl links are converted to oxo links, and the gel's reactivity decreases. Upon heating to 500 °C the gel yields monoclinic or metastable tetragonal oxide, or a mixture of these. The specific structure obtained has been attributed to the precursor zirconium salt [46], pH of the liquid in final contact with the condensed gel [47], electronegativity and pH [48], slow or rapid condensation from sol to gel, ageing, the presence during gelling of sulfate, sodium, potassium, or ammonium ions, and particle size [49].

Hydrous zirconium oxide in controlled particle size is prepared by hydrolysis of sodium zirconate [50].

Hydrous zirconium oxide sol is used in sol – gel processes to produce stabilized zirconias in spherical or fibrous form, and to form an oxidation-protective film on stainless steels.

2.4. Zirconium Chlorides

The fully chlorinated form of zirconium is zirconium tetrachloride. The tetrachloride is normally produced by carbochlorination of zircon or zirconia [51] (see page 6) or by reacting zirconium metal with chlorine or hydrogen chloride. Chlorinated hydrocarbons, particularly carbon tetrachloride, chloroform, or hexachloroethane, are useful laboratory chlorinating agents. Zirconium tetrachloride can be formed by reacting ferrozirconium or silicozirconium with iron(II) chloride at elevated temperature [52].

Zirconium tetrachloride vapor is a tetrahedral monomer which crystallizes below 331 °C in a AB_4 type structure with $ZrCl_6$ octahedra coupled to each other by two edges to form a zig-zag chain. Each zirconium has four bridging chlorine ligands and two terminal chlorines which are mutually *cis* [53]. Some physical properties of zirconium tetrachloride are shown in Table 4.

Zirconium tetrachloride reacts rapidly with water, vapor or liquid, to exchange two chlorines for oxygen. Any handling of zirconium tetrachloride must be in moisture-free atmospheres to avoid degradation. Zirconium tetrachloride powder fed into water hydrolyzes to form a solution of zirconium hydroxide chloride and free hydrochloric acid. Zirconium tetrachloride vapor reacts with steam to yield zirconium oxide, and reacts with water to yield either an oxide slurry or hydroxide chloride solution.

Zirconium tetrachloride is used to form zirconium nitride coatings, to react electrochemically to form zirconia in high-temperature fuel cells, to react with alcohols to form alkoxides, and to produce zirconium organometallic compounds. Zirconium tetrachloride is reduced by molten alkali and alkaline earth metals, yielding zirconium metal.

Zirconium tetrachloride reacts reversibly with ammonium chloride, alkali metal chlorides, and alkaline earth chlorides to form hexachlorozirconates [54], [55]. Zirconium tetrachloride forms addition compounds with aluminum and iron trichlorides and phosphorus pentachloride, but $FeZrCl_6$ dissociates to $FeCl_2$ and $ZrCl_4$ above 350 °C.

Lower valent zirconium chlorides including zirconium trichloride [*10241-03-9*], dichloride [*13762-26-0*], monochloride [*14989-34-5*] and zirconium chloride cluster phases Zr_6Zl_{12} and Zr_6Cl_{15} are produced by reduction of zirconium tetrachloride with zirconium metal or with zirconium monochloride in sealed tantalum containers. The reactions are slow, usually requiring weeks at 300 to 800 °C [56–58]. Zirconium monochloride reacts reversibly with hydrogen at 340 °C in a sealed tube to form $ZrClH_x$ ($x \leq 1$) [59].

2.5. Zirconium Hydroxide Chlorides

Zirconium hydroxide dichloride [*22196-48-1*], empirically $Zr(OH)_2Cl_2 \cdot 7\,H_2O$, has been known by several names: zirconyl chloride, zirconium oxychloride, zirconium oxide dichloride, all commonly identified as $ZrOCl_2 \cdot 8\,H_2O$. Structurally the hydroxide dichloride is really $[Zr_4(OH)_8 \cdot 16\,H_2O]Cl_8 \cdot 12\,H_2O$ [60].

Zirconium hydroxide dichloride solution is formed by dissolving hydrous zirconium oxide or zirconium carbonate in hot hydrochloric acid, or by hydrolysis of zirconium tetrachloride in water. The solubility in hot water is quite high and the solubility is decreased by cooling and by adding hydrochloric acid. Excellent recoveries are obtained by crystallization ending with a 6 N hydrochloric acid mother liquor. This crystallization procedure also leaves most impurities dissolved in the mother liquor. Crystallization may be repeated to obtain very pure crystals.

Zirconium hydroxide dichloride crystals dissolve in their hydration water on gentle heating, and readily lose the hydrates outside the tetramer unit. With continued heating both water and hydrogen chloride are evolved until zirconium oxide remains [61], [62].

Zirconium hydroxide monochloride $[Zr_4(OH)_{12} \cdot 16\,H_2O]Cl_4$ is formed in solution by reacting equimolar portions of zirconium hydroxide dichloride and hydrous zirconium oxide or zirconium basic carbonate, or by the action of

Table 4. Physical properties of zirconium tetrahalides

hydrogen peroxide upon zirconium hydroxide dichloride [63].

Anhydrous zirconium oxide chlorides have been prepared: the reaction of zirconium dioxide with zirconium monochloride at 980 °C produced $ZrClO_y$ ($y < 0.42$) [64]. The reaction of zirconium tetrachloride powder in carbon tetrachloride with dichlorine oxide at −30 °C yielded $ZrOCl_2$, which dissociated to $ZrCl_4$ and ZrO_2 above 200 °C [65].

2.6. Zirconium Bromides

Zirconium tetrabromide, $ZrBr_4$, can be prepared by heating zirconium metal or carbide above 400 °C in a stream of bromine, or similarly a fine mixture of zirconium oxide and carbon at 900 °C. Its behavior is similar to zirconium tetrachloride but, because of its higher cost, the tetrabromide is of little commercial interest. Some physical properties are shown in Table 4.

Zirconium tribromide [*24621-18-9*], zirconium dibromide [*24621-17-8*], zirconium monobromide [*31483-18-8*], and zirconium monobromide hydride [*60921-40-6*] can be made by the same procedures used for their chloride analogues [66].

2.7. Zirconium Iodides

Zirconium tetraiodide, ZrI_4, is important because of its use in the van Arkel – de Boer refining process (see Section 1.4.4). The tetraiodide cannot be produced by heating fine zirconium oxide and carbon in iodine vapor, but is produced by heating zirconium metal to 300 °C in iodine. A temperature of ca. 1000 °C is required for a reasonably rapid reaction of iodine with zirconium carbide, carbonitride, or nitride. Zirconium tetraiodide is oxidized by dry air at about 200 °C. Some physical properties are shown in Table 4.

Lower-valence iodides have been made by reduction of zirconium tetraiodide with zirconium in sealed tantalum tubes or with zirconium or aluminum in aluminum iodide solvent [67]. Compounds formed include zirconium triiodide [*13779-87-8*], zirconium diiodide [*15513-85-6*] (both α monoclinic and β orthorhombic form), zirconium clusters Zr_6I_{12} [*66908-75-6*], and zirconium monoiodide [*14728-76-8*] [68].

2.8. Zirconium Fluorides

There are several methods for the production of zirconium tetrafluoride, ZrF_4. Anhydrous zirconium tetrafluoride is produced in good purity by mixing hydrogen fluoride gas and zirconium tetrachloride vapor at 350 °C [69]. The hydrofluorination of zirconium oxide proceeds rapidly at 25 °C, followed by a purifying sublimation in dry hydrogen fluoride at 825 °C [70]. Zirconium tetrafluoride monohydrate is precipitated by adding strong hydrofluoric acid to a concentrated zirconium nitrate/nitric acid solution. The filtered crystals are washed with nitric acid, dried, and dehydrated with hydrogen fluoride at 450 °C [71]. Zirconium metal or zirconium hydride can be fluorinated with hydrogen fluoride but unless the reaction is conducted above 800 °C, the tetrafluoride products coats the metal, impeding the reaction. Zirconium oxides mixed with ammonium hydrogen difluoride and heated to 200 °C yield ammonium heptafluorozirconate [*17250-81-6*], $(NH_4)_3ZrF_7$, which on heating to 500 °C gives off ammonium flu-

oride. Some physical properties of zirconium tetrafluoride are shown in Table 4.

Zirconium tetrafluoride is hydrolysed in water to a hydroxide fluoride $Zr_4(OH)_6F_{10} \cdot 3\,H_2O$ with limited solubility. With increasing hydrofluoric acid concentration, $ZrF_4 \cdot 3\,H_2O$ crystallizes at 30 – 35 wt % HF, $HZrF_5 \cdot 4\,H_2O$ at 30 – 35 wt % HF, and $H_2ZrF_6 \cdot 2\,H_2O$ at 40 – 60 wt % HF. In strong nitric or sulfuric acid containing excess hydrofluoric acid, the monohydrate crystallizes. Heating these hydrates produces $ZrOF_2$ at 300 °C.

Very high purity anhydrous zirconium tetrafluoride is a major constituent of some fluoride glasses, particularly ZBLAN, being developed because their transparency for near UV to mid IR (0.3 – 6 µm) was projected to be better than that of quartz optical fiber.

Potassium hexafluorozirconate production by fluorosilicate fusion is described in Section 1.6. This compound has been used to introduce zirconium into molten aluminum and magnesium as a grain refiner.

As mentioned in Section 1.7, zirconium metal is customarily pickled in dilute hydrofluoric acid/nitric acid solution. To minimize fluoride waste discharge the pickling solution is regenerated by adding sodium fluoride to precipitate sodium fluorozirconates. The particular salt precipitated varies with the sodium fluoride concentration: $NaZrF_5 \cdot H_2O$ is precipitated when the sodium fluoride concentration is less than 0.21 %, and Na_2ZrF_6 is precipitated if the sodium fluoride concentration is between 0.21 and 0.4 %. At higher sodium fluoride concentration $Na_5Zr_2F_{13}$ and Na_3ZrF_7 precipitate.

Zirconium tetrafluoride forms many double fluoride compounds in different proportions with alkali fluorides, alkaline earth fluorides, and others as diverse as stannous hexafluorozirconate and zirconium hexafluorogermanate, both proposed for caries prophylaxis.

2.9. Zirconium Sulfates

The sulfates of zirconium are classified as anionic, normal, or basic, depending on the sulfate to zirconium ratio. For anionic complexes this ratio is >2. Normal sulfates have a ratio of exactly two, and basic sulfates have less than two sulfates per zirconium. Basic sulfates made by hydrolysis of neutral sulfates usually have a ratio >1, while basic sulfates precipitated by adding sulfate ions to hot dilute solutions of zirconium hydroxide chloride have a ratio <1, usually 0.4 – 0.7.

Zirconium sulfate solutions can be generated by the action of strong sulfuric acid on hydrous zirconium oxide, zirconium oxide, zirconium carbonitride, zirconium metal, or basic zirconium sulfate. Normal zirconium sulfate [*7446-31-3*], $Zr(SO_4)_2 \cdot 4\,H_2O$, also known as zirconium orthosulfate, can be crystallized from the above solution, or from a zirconium hydroxide chloride solution by adding sulfuric acid up to a concentration of 45 % and allowing the solution to cool below 60 °C. A better purification is obtained during the crystallization if the solution contains some chloride ion.

Ammonium zirconium sulfates can be prepared by heating zirconium oxide with ammonium sulfate at 400 °C [72] or by precipitation from a zirconium sulfate solution [73]. A crude sodium zirconium sulfate can be prepared by adding sulfuric acid to sodium zirconate. Structure and composition of many sulfate variants are discussed in [30], [74], [75].

Basic zirconium sulfates containing less than one sulfate per zirconium are precipitated from hot acidic solutions of zirconium hydroxide chloride by adding 0.4 – 0.6 mol of sulfate per zirconium. The stoichiometric formula is $Zr_5O_{(10-x)}(SO_4)_x$ (x=1.8 – 3.5). The most common basic sulfate is $Zr_5O_7(SO_4)_3 \cdot n\,H_2O$.

Normal zirconium sulfate is used for leather tanning, as a catalyst, to coat titanium oxide pigment powder, and for conversion to other zirconium chemicals. The basic sulfate is converted into other zirconium chemicals, many retaining the particle size developed during the controlled precipitation of the basic sulfate.

2.10. Zirconium Carbonates

Basic zirconium carbonate [*37356-18-6*] is produced by adding basic zirconium sulfate to a sodium carbonate solution, and filtering the insoluble basic carbonate. The empirical formula is $ZrO_2 \cdot CO_2 \cdot x\,H_2O$ but the zirconium to carbonate ratio varies considerably.

The basic carbonate is reacted with organic acids to make soluble zirconium salts, such as the citrate, oxalate, and acetate, free of chloride and sulfate ions. The carbonate is used to make a zirconium – aluminum – glycine complex, an active ingredient of antiperspirant formulations.

Zirconium basic carbonate is added to potassium carbonate or ammonium carbonate solutions to make water-soluble double carbonates. At room temperature, these solutions hydrolyze so slowly that they are considered to be stable for a month, but on heating carbon dioxide evolves and insoluble hydrous zirconium oxide forms. Ammonium zirconium carbonate [*22829-17-0*], empirically $(NH_4)_3[Zr_2O(OH)_3(CO_3)_3]$, is used extensively in bonding starch onto coated paper [76], and in controlling pitch deposition in pulp and papermaking systems [77].

2.11. Zirconium Hydride

Zirconium hydride [*7704-99-6*], ZrH_2, is prepared by the reversible absorption of hydrogen into heated zirconium, usually sponge or ingot slices. The metal is heated above 600 °C in an inert atmosphere or vacuum to dissolve the surface oxide film, then hydrogen is introduced. At 600 °C, hydrogen dissolves into the α-phase metal up to 6 atom %, when β-Zr appears. (Hydrogen is a β-phase stabilizer, lowering the transformation temperature from 863 °C to 550 °C.) At 40 atom % the solubility in β-Zr is exceeded and δ-phase hydride appears. At 60 – 64 atom % only δ-phase exists. Above 64 at. % the tetragonal ε-phase is stable [78]. To obtain fully hydrided ZrH_2 the charge is cooled to 300 °C in full hydrogen atmosphere.

The reduction of zirconium oxide with calcium hydride yields a fine (2 – 5 µm particles) hydride powder for use in pyrotechnics such as fuses or fireworks:

$$ZrO_2 + 2\,CaH_2 \rightarrow ZrH_2 + 2\,CaO + H_2$$

Extreme care must be used in dissolving the calcium oxide to recover the hydride powder.

Hydriding of zirconium sponge or ingot is the first step in producing coarse zirconium powder for powder metallurgy applications. Hydrided metal begins to lose its ductility above 40 atom % hydrogen, and above 60 atom % the hydrided metal is quite brittle and suitable for crushing, which is conducted in an inert atmosphere. During hydriding, the metal density decreases with increasing hydrogen content, going from 6.5 to 5.6 when fully hydrided.

Zirconium hydride loses hydrogen upon heating. For complete dehydriding the powder must be heated under vacuum (e.g., 700 °C until the vacuum falls to 10^{-3} Pa). Dehydriding is faster at higher temperatures but the powder begins to sinter.

Zirconium hydride contains about the same number of hydrogen atoms per volume as room-temperature water, and some alloys such as ZrNi and $ZrCr_2$ can hold even more [79]. Zirconium hydride has been used in the nuclear industry as a moderator for thermal neutrons in compact, high-temperature reactors. Zirconium hydride is of interest for hydrogen storage and nickel-base hydrogen battery applications.

Zirconium hydride is inert to air and water at room temperature. It ignites in air at 340 °C or lower, depending on powder size. Zirconium hydride is resistant to corrosion by carbon dioxide up to 315 °C.

Zirconium hydride heated with carbon yields the hexagonal zirconium carbohydride, $ZrC \cdot ZrH_{1.46}$ [80]. Zirconium monochloride reversibly absorbs hydrogen up to ZrClH [81].

2.12. Zirconium Carbide

Zirconium carbide [*12020-14-3*], ZrC, is a hard, brittle metallic carbide. It is an electrical conductor and does not hydrolyze in water. It is an interstitial carbide with the carbon atoms occupying the octahedral interstices of the zirconium lattice, at 2000 °C, carbon is soluble in liquid zirconium up to 38.5 atom %. Zirconium carbide is a single phase within the concentration range of 38.5 – 49.4 atom % carbon with a congruent composition of 44 atom % carbon at the melting point of 3445 °C [82], [83].

Zirconium carbide can be produced from zircon by reduction with coke in electric arc furnaces [84]. An intimate mix of fine zirconium oxide and carbon black heated in vacuum or hydrogen in an induction-heated graphite crucible at 1600 °C yields a porous, light zirconium carbide. Milling and refiring above 2200 °C gives

a dense powder. Zirconium tetrachloride and methane in a hydrogen atmosphere are heated to 1200 °C to deposit zirconium carbide films on tool bits. Pure zirconium metal powder and fine graphite powder react exothermically, once ignited, to form zirconium carbide, usually to form a composite with an excess of one reagent.

2.13. Zirconium Nitrides

Zirconium nitride [*25658-42-8*], ZrN, is a golden-colored, hard, brittle metallic nitride. It is thermally and chemically stable, and has low resistivity. As with the carbide it is an interstitial compound with a NaCl cubic structure. At 2000 °C, nitrogen is soluble in liquid zirconium up to 39 atom % nitrogen. Zirconium nitride is a single phase within the concentration range of 39 – 50 atom % nitrogen [85], [86]. While 3253 K is the accepted melting point of zirconium nitride, the melting temperature of 3970 K as measured in a positive pressure of nitrogen [87] is compatible with a thermodynamic study of the Zr – N system.

Zirconium nitride has been made by heating zirconium or zirconium hydride powder in nitrogen at 1000 °C, and by heating a zirconium oxide/carbon mixture in a nitrogen atmosphere. The reaction of zirconium tetrachloride with ammonia or nitrogen and hydrogen has been used to produce nitride powder and to deposit coherent films on substrates at 1000 – 1200 °C. Very limited quantities of nitride have been made by the very exothermic reaction of lithium nitride and zirconium tetrachloride powders [88].

Metastable Zr_3N_4 has been made by dual ion beam deposition [89] and by reacting zirconium tetraiodide with ammonia at 500 °C and heating the product to Zr_3N_4 at 700 °C [90]. On further heating to 1000 °C ZrN is formed. Thin films of Zr_3N_4 have been grown by passing ammonia and tetrakis(diethylamido)zirconium over substrates at 200 – 400 °C [91].

Zirconium nitride has been used as a wear-resistant coating on steel drill bits and cemented-carbide tool bits, as decorative coating, as a protective coating on steel vessels handling molten metal, and as solar energy collector surface film.

2.14. Zirconium Borides

While three zirconium borides, ZrB, ZrB_2 and ZrB_{12}, are found in the zirconium – boron system, only the diboride is chemically and thermally stable. Zirconium diboride [*12045-64-6*] is a gray refractory solid with a hexagonal crystal structure and a very high melting point of 3245 °C. Technical-quality zirconium diboride can be prepared by reacting zircon, boron oxide, and carbon in a submerged-electrode arc furnace [92]. Purer diboride can be produced by co-reduction of zirconium tetrachloride and boron trichloride with hydrogen or aluminum in a chloride bath. Zirconium diboride films can be produced by subliming zirconium tetrahydridoborate at 25 °C in a vacuum and passing the vapor over a substrate heated to 250 °C.

Zirconium diboride has high hardness, good oxidation resistance, and excellent thermal-shock resistance. It has been used as a diffusion barrier in semiconductors, as a container for molten metals, and as a burnable absorber in nuclear reactor cores.

2.15. Zirconium Tetrahydridoborate

Zirconium tetrahydridoborate [*12370-59-1*], $Zr(BH_4)_4$, is prepared by reaction of zirconium tetrachloride with lithium tetrahydridoborate in diethyl ether, followed by double distillation at 20 °C [93]. It has a tetrahedral structure with three hydrogen atoms bridging the zirconium atom and each boron atom. Zirconium tetrahydridoborate is one of the most volatile zirconium compounds known: *mp* 29 °C; *bp* 118 °C; vapor pressure 2 kPa at 25 °C. Its decomposition near 250 °C forms the basis for a low-temperature method of depositing zirconium boride films. Zirconium tetrahydridoborate catalyzes the polymerization of unsaturated hydrocarbons. It reacts with aliphatic alcohols to form zirconium and boron alkoxides [94]. Zirconium tetrahydroborate inflames on contact with dry air.

2.16. Zirconium Tungstate

Zirconium tungstate is precipitated as a white gel by simultaneous addition of dilute solutions

of sodium tungstate and zirconium hydroxide dichloride to vigorously stirred water. After acidification the slurry is refluxed. The dried and fired product is ZrW_2O_8 [95]. Other studies indicate that ZrW_2O_8 formed by the reaction of a mixture of ZrO_2 and WO_3 which is held between 1100 and 1400 °C for at least 24 h melts incongruently at 1257 °C and dissociates below 1105 °C [96]. ZrW_2O_8 is an unusual compound which contracts equally in each dimension when it is heated over the temperature range 1 – 1050 K [97].

2.17. Zirconium Phosphate

Insoluble, amorphous zirconium phosphate is obtained when a zirconium salt is added to an excess of phosphoric acid. If the original salt was solid rather than in solution, the resulting phosphate will have a similar physical size and shape: i.e., beads, granules, fibers. Refluxing the precipitate in strong phosphoric acid gives a crystalline product of constant composition, $Zr(HPO_4)_2 \cdot H_2O$. Zirconium bis(monohydrogenphosphate) with one water of hydration is known as α-zirconium phosphate. Below 80 °C a second water of hydration is added to form γ-zirconium phosphate. On heating α-zirconium phosphate, the water is lost between 300 and 650 °C, leaving β-zirconium phosphate. Conversion to zirconium pyrophosphate, ZrP_2O_7, occurs between 800 and 920 °C [98].

Zirconium bis(monohydrogenphosphate) has ion exchange properties and, because of its structure and bonding between layers, can also act as an intercalation compound [99]. Zirconium phosphate shows excellent catalytic activity for the selective condensation of acetone to mesityl oxide, and when palladium is deposited on the phosphate surface the combination is an effective catalyst for the direct synthesis of methyl isobutyl ketone from acetone and hydrogen [100].

The addition of univalent ions Li, Na, K and compensating trivalent ions In, Y, Eu into ZrP_2O_7 produces a solid electrolyte [101]. Ultralow thermal expansion ceramics have been developed in the $Na_2O - ZrO_2 - P_2O_5 - SiO_2$ system [102], while the addition of vanadium to sodium zirconium pyrophosphate: $Na_2PrP_{2-x}V_xO_7$ yields a ceramic which shrinks when heated above 60 °C [103].

2.18. Zirconium Nitrates

Zirconium hydroxide dinitrate, [*20213-65-4*], $Zr(OH)_2(NO_3)_2$, is formed by dissolving hydrous zirconium oxide in nitric acid or by dissolving zirconium hydroxide dichloride in nitric acid and distilling off the chlorine.

Zirconium tetranitrate [*12372-57-5*], $Zr(NO_3)_4 \cdot 5\,H_2O$, can be precipitated from strong nitric acid at low temperature, less than 15 °C [104].

2.19. Zirconium Carboxylates

Zirconium hydroxide carboxylates form upon adding carboxylate salts to a solution of zirconium dihydroxide chloride, or carboxylic acids to zirconium basic carbonate. The general formula is $Zr(OH)_{4-n}(OOR)_n$, where n is 1 – 3 usually.

When zirconium basic carbonate paste is slowly stirred into a mineral spirit solution of octanoic acid, a solution of zirconium dihydroxide octanoate is produced which is of use in oil-based paints as a dryer catalyst.

Short-chain carboxylates may be soluble, i.e., zirconium dihydroxide diacetate. Longer aliphatic chain carboxylates (zirconium soaps) are water insoluble [105].

2.20. Zirconium Alkoxides

Zirconium alkoxides are prepared by adding zirconium tetrachloride to anhydrous alcohols [106]:

$$ZrCl_4 + C_3H_7OH \rightarrow ZrCl_2(OC_3H_7)_2 \cdot C_3H_7OH + 2\,HCl$$

If there is no steric hindrance, all four chlorines can be exchanged if ammonia is added to combine with the hydrogen chloride.

Alkoxides of different alcohols can be formed by alcohol exchange. This can be facilitated by removal of the more volatile alcohol, or a lower-boiling azeotrope with an inert solvent such as benzene. The conversion of zirconium

tetramethoxide by refluxing with tertiary butanol proceeds only to zirconium methoxide tri-*tert*-butoxide because of steric factors. The following order was found in the interchange of alkoxy groups:

$$MeO > EtO > Pr^{i}O > Bu^{t}O$$

The reaction of *tert*-butanol with zirconium tetrahydridoborate yielded a double alkoxide complex of zirconium *tert*-butoxide with bis(*tert*-butoxy) borane [94].

Zirconium alkoxides hydrolyze quite easily. This provides a route to high-purity, high-surface-area zirconium oxide.

3. Analysis

Analysis for zirconium in ore, soil, vegetation in compounds, and as a minor alloying constituent involves bringing the zirconium into solution, then precipitating with mandelic acid [107] and firing the precipitate to oxide. For the determination of zirconium in air samples, plasma emission spectroscopy is used.

Methods to determine the hafnium associated with the zirconium include atomic absorption spectroscopy, emission spectroscopy, mass spectroscopy, X-ray spectroscopy, and neutron activation.

Most impurities in zirconium and zirconium compounds are determined by emission spectroscopy, with arc-spark [108] or plasma excitation [109], [110]. Atomic absorption is also used to determine a variety of impurities [111].

Carbon and sulfur in zirconium are measured by combustion followed by chromatographic or IR determination of the oxides [112]. Hydrogen is determined by thermal conductivity after hot-vacuum extraction, or by fusion of zirconium with a transition metal in an inert atmosphere and subsequent separation by gas chromatography [113], [114].

Simultaneous determination of oxygen and nitrogen is accomplished by fusion of zirconium with a transition metal in the presence of carbon in an inert atmosphere and subsequent separation by gas chromatography [115], [116]. Nitrogen can be determined by the Kjeldahl technique [112].

Phosphorus may be determined by visible spectrophotometry using molybdenum blue [112] but can be determined more rapidly by phosphine evolution and flame emission spectroscopy.

Chloride at low level is determined indirectly by precipitation with silver nitrate and determination of the silver by X-ray or atomic absorption spectroscopy. Fluoride and higher levels of chloride can be measured by selective ion electrode techniques [117], [118].

4. Toxicology

Zirconium and its compounds are generally of low toxicity. However, the strongly acidic compounds such as zirconium tetrabromide, zirconium tetrachloride, zirconium tetrafluoride, zirconium tetraiodide, zirconium tetranitrate and zirconium sulfate are strongly corrosive to eyes, lungs, skin, mouth, esophagus, and stomach. Exposure to these compounds should be avoided, not because they contain zirconium, but because of the acidic nature of their hydrolysis products generated upon contact with animal or plant tissue.

Inhalation of zirconium materials in the workplace has not resulted in significant toxicity in 40 years of considerable exposure if reasonable care was used. One case of pulmonary fibrosis, believed to have been induced by heavy and continued exposure to zirconium oxide dust while preparing slurries for lens polishing, developed after a 15-year latency period [119]. Severe respiratory tract irritation from inhaling zirconium acetoacetonate disappeared after exposure ceased [120]. In 1978 the FDA banned the production of antiperspirant aerosols containing zirconium because of concern about possible lung granulomas.

Inhalation laboratory tests with insoluble zirconium oxide varied. Some showed no effect, some caused fibrosis. Russian tests with the insoluble compounds zirconium boride [121] and zirconium hydride [122] both showed fibrogenic action in the lungs of albino rats. Aerosols of soluble zirconium dihydroxide chloride and zirconium dihydroxide nitrate each caused intense irritation of upper breathing passages similar to the action of strong acid. The animals died with 30 – 40 min. Sodium zirconium lactate caused

lung granulomatosis in rabbits [123], and it is indicated that a complex of zirconium chlorhydrate and aluminum chlorhydrate also induces granulomatous lung changes [124].

Antiperspirants and poison ivy remedies containing zirconium have caused skin granulomas as a delayed hypersensitivity reaction in a few users [125].

Toxicity tests on laboratory animals showed that the acute toxicity of inorganic zirconium salts is very low when administered orally. Administered intraperitoneally, both organic and inorganic compounds were 2 – 20 times more toxic.

An excellent summation of zirconium toxicology through 1975 is available [126]. Toxicity data for some zirconium compounds is shown in Table 5.

Table 5. Toxicity data (rat) for some zirconium compounds [127]

Compound	Oral LD_{50}, mg/kg	Inhalation LCLo mg/m^3
Dihydroxide chloride	3500	500 for 30 min
Dihydroxide nitrate	2290	500 for 30 min
Sulfate	3500	
Tetrachloride	1688	3124 ppm HCl for 1 hour
Acetate	4100	

The OSHA exposure limit for zirconium and zirconium compounds as airborne particulate is 5 mg/m^3 TWA and 10 mg/m^3 STEL, as zirconium. In Germany, the MAK is 5 mg/m^3 as zirconium. In Russia, MAK is 6 mg/m^3 as zirconium.

5. Storage and Transportation

High-surface-area zirconium metal such as sponge or powder is a combustible solid which should be kept dry and stored away from sources of ignition and oxidizers.

The Department of Transportation has classified all dry zirconium powder as "spontaneously combustible", hazard class 4.2, with identification number UN 2008. The powders are subdivided into packing group I, II, or III, as evaluated by their burning rate in a standardized testing procedure. Group I is for very fine zirconium powder which is a pyrophoric material. Group I powder may not be shipped by air.

Some zirconium powder, usually fuse powder, is recovered wet and shipped wet. This powder is classified as a flammable solid, hazard class 4.1, UN 1358.

Zirconium hydride is classified as a flammable solid, hazard class 4.1, UN 1437.

Zirconium nitrate is classified as an oxidizer, hazard class 5.1, UN 2728.

Zirconium sulfate is classified as corrosive, hazard class 8, NA 9163.

Zirconium tetrachloride is classified as corrosive, hazard class 8, UN 2503.

Variables

a	1, 2, or 3 for planar, cylindrical, spherical geometry
a_i	acceleration of i-th particle in molecular dynamics
A	cross-sectional area of reactor; Helmholtz free energy in thermodynamics
Bi	Biot number
Bim	Biot number for mass
c	concentration
C_p	heat capacity at constant pressure
C_s	heat capacity of solid
C_v	heat capacity at constant volume
Co	Courant number
D	diffusion coefficient
Da	Damköhler number
D_e	effective diffusivity in porous catalyst
E	efficiency of tray in distillation column
F	molar flow rate into a chemical reactor
G	Gibbs free energy in thermodynamics
h_p	heat transfer coefficient
H	enthalpy in thermodynamics
J	mass flux
k	thermal conductivity; reaction rate constant
k_e	effective thermal conductivity of porous catalyst
k_g	mass transfer coefficient
K	chemical equilibrium constant
L	thickness of slab; liquid flow rate in distillation column; length of pipe for flow in pipe
m_i	mass of i-th particle in molecular dynamics
M	holdup on tray of distillation column
n	power-law exponent in viscosity formula for polymers
p	pressure
Pe	Peclet number
q	heat flux
Q	volumetric flow rate; rate of heat generation for heat transfer problems
r	radial position in cylinder
$\boldsymbol{r}_i$	position of i-th particle in molecular dynamics
R	radius of reactor or catalyst pellet
Re	Reynolds number
S	entropy in thermodynamics
Sh	Sherwood number
t	time
T	temperature
$\boldsymbol{u}$	velocity
U	internal energyy in thermodynamics
$\boldsymbol{v}_i$	velocity of i-th particle in molecular dynamics
V	volume of chemical reactor; vapor flow rate in distillation column; potential energy in molecular dynamics; specific volume in thermodynamics
x	position
z	position from inlet of reactor

Greek symbols

a	thermal diffusivity
δ	Kronecker delta
Δ	sampling rate
ε	porosity of catalyst pellet
η	viscosity in fluid flow; effectiveness factor for reaction in a catalyst pellet
η_0	zero-shear rate viscosity
ϕ	Thiele modulus
φ	void fraction of packed bed
λ	time constant in polymer flow
ρ	density
ρ_s	density of solid
τ	shear stress
μ	viscosity

Special symbols

$\vert$	subject to
:	mapping. For example, $h: R^n \to R^m$, states that functions h map real numbers into m real numbers. There are m functions h written in terms of n variables
$\in$	member of
$\to$	maps into

1. Solution of Equations

Mathematical models of chemical engineering systems can take many forms: they can be sets of algebraic equations, differential equations, and/or integral equations. Mass and energy balances of chemical processes typically lead to large sets of *algebraic* equations:

$$a_{11}x_1 + a_{12}x_2 = b_1$$
$$a_{21}x_1 + a_{22}x_2 = b_2$$

Mass balances of stirred tank reactors may lead to ordinary *differential* equations:

$$\frac{\mathrm{d}\,y}{\mathrm{d}\,t} = f\ [y\,(t)]$$

Radiative heat transfer may lead to *integral equations:*

$$y\,(x) = g\,(x) + \lambda \int_0^1 K\,(x, s)\, f\ (s)\,\mathrm{d}\,s$$

Even when the model is a differential equation or integral equation, the most basic step in the algorithm is the solution of sets of algebraic equations. The solution of sets of algebraic equations is the focus of Chapter 1.

A single linear equation is easy to solve for either x or y:

$$y = ax + b$$

If the equation is nonlinear,

$$f\,(x) = 0$$

it may be more difficult to find the x satisfying this equation. These problems are compounded when there are more unknowns, leading to simultaneous equations. If the unknowns appear in a linear fashion, then an important consideration is the structure of the matrix representing the equations; special methods are presented here for special structures. They are useful because they increase the speed of solution. If the unknowns appear in a nonlinear fashion, the problem is much more difficult. Iterative techniques must be used (i.e., make a guess of the solution and try to improve the guess). An important question then is whether such an iterative scheme converges. Other important types of equations are linear difference equations and eigenvalue problems, which are also discussed.

1.1. Matrix Properties

A matrix is a set of real or complex numbers arranged in a rectangular array.

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}$$

The numbers a_{ij} are the elements of the matrix $\boldsymbol{A}$, or $(\mathrm{A})_{ij} = a_{ij}$. The transpose of $\boldsymbol{A}$ is $(\boldsymbol{A}^T) = a_{ji}$.

The determinant of a square matrix $\boldsymbol{A}$ is

$$\boldsymbol{A} = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix}$$

If the i-th row and j-th column are deleted, a new determinant is formed having $n-1$ rows and columns. This determinant is called the minor of a_{ij} denoted as M_{ij}. The cofactor A'_{ij} of the element a_{ij} is the signed minor of a_{ij} determined by

$$A'_{ij} = (-1)^{i+j} M_{ij}$$

The value of $|\boldsymbol{A}|$ is given by

$$|\boldsymbol{A}| = \sum_{j=1}^{n} a_{ij} A'_{ij} \text{ or } \sum_{i=1}^{n} a_{ij} A'_{ij}$$

where the elements a_{ij} must be taken from a single row or column of $\boldsymbol{A}$.

If all determinants formed by striking out whole rows or whole columns of order greater than r are zero, but there is at least one determinant of order r which is not zero, the matrix has rank r.

The value of a determinant is not changed if the rows and columns are interchanged. If the elements of one row (or one column) of a determinant are all zero, the value of the determinant is zero. If the elements of one row or column are multiplied by the same constant, the determinant is the previous value times that constant. If two adjacent rows (or columns) are interchanged, the value of the new determinant is the negative of the value of the original determinant. If two rows (or columns) are identical, the determinant is zero. The value of a determinant is not changed if one row (or column) is multiplied by a constant and added to another row (or column).

A matrix is *symmetric* if

$$a_{ij}=a_{ji}$$

and it is *positive definite* if

$$\boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x}=\sum_{i=1}^{n}\sum_{j=1}^{n}a_{ij}x_ix_j\geq 0$$

for all $\boldsymbol{x}$ and the equality holds only if $\boldsymbol{x}=0$.

If the elements of $\boldsymbol{A}$ are complex numbers, $\boldsymbol{A}^*$ denotes the complex conjugate in which $(A^*)_{ij}=a^*_{ij}$. If $\boldsymbol{A}=\boldsymbol{A}^*$ the matrix is Hermitian.

The *inverse of a matrix* can also be used to solve sets of linear equations. The inverse is a matrix such that when $\boldsymbol{A}$ is multiplied by its inverse the result is the identity matrix, a matrix with 1.0 along the main diagonal and zero elsewhere.

$$\boldsymbol{A}\boldsymbol{A}^{-1}=\boldsymbol{I}$$

If $\boldsymbol{A}^T=\boldsymbol{A}^{-1}$ the matrix is orthogonal.

Matrices are added and subtracted element by element.

$$\boldsymbol{A}+\boldsymbol{B} \text{ is } a_{ij}+b_{ij}$$

Two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are equal if $a_{ij}=b_{ij}$. Special relations are

$$(\boldsymbol{AB})^{-1}=\boldsymbol{B}^{-1}\boldsymbol{A}^{-1},\quad (\boldsymbol{AB})^T=\boldsymbol{B}^T\boldsymbol{A}^T$$
$$(\boldsymbol{A}^{-1})^T=(\boldsymbol{A}^T)^{-1},\quad (\boldsymbol{ABC})^{-1}=\boldsymbol{C}^{-1}\boldsymbol{B}^{-1}\boldsymbol{A}^{-1}$$

A diagonal matrix is zero except for elements along the diagonal.

$$a_{ij}=\begin{cases} a_{ii}, & i=j \\ 0, & i\neq j \end{cases}$$

A tridiagonal matrix is zero except for elements along the diagonal and one element to the right and left of the diagonal.

$$a_{ij}=\begin{cases} 0 \text{ if } j<i-1 \\ a_{ij} \text{ otherwise} \\ 0 \text{ if } j>i+1 \end{cases}$$

Block diagonal and pentadiagonal matrices also arise, especially when solving partial differential equations in two- and three-dimensions.

QR Factorization of a Matrix. If A is an $m\times n$ matrix with $m\geq n$, there exists an $m\times m$ unitary matrix $\boldsymbol{Q}=[\boldsymbol{q}_1,\boldsymbol{q}_2,\ldots\boldsymbol{q}_m]$ and an $m\times n$ right-triangular matrix $\boldsymbol{R}$ such that $\boldsymbol{A}=\boldsymbol{QR}$. The QR factorization is frequently used in the actual computations when the other transformations are unstable.

Singular Value Decomposition. If $\boldsymbol{A}$ is an $m\times n$ matrix with $m\geq n$ and rank $k\leq n$, consider the two following matrices.

$$\boldsymbol{A}\boldsymbol{A}^* \text{ and } \boldsymbol{A}^*\boldsymbol{A}$$

An $m\times m$ unitary matrix $\boldsymbol{U}$ is formed from the eigenvectors $\boldsymbol{u}_i$ of the first matrix.

$$\boldsymbol{U}=[\boldsymbol{u}_1,\boldsymbol{u}_2,\ldots\boldsymbol{u}_m]$$

An $n\times n$ unitary matrix $\boldsymbol{V}$ is formed from the eigenvectors $\boldsymbol{v}_i$ of the second matrix.

$$\boldsymbol{V}=[\boldsymbol{v}_1,\boldsymbol{v}_2,\ldots,\boldsymbol{v}_n]$$

Then the matrix $\boldsymbol{A}$ can be decomposed into

$$\boldsymbol{A}=\boldsymbol{U}\Sigma\boldsymbol{V}^*$$

where Σ is a $k\times k$ diagonal matrix with diagonal elements $d_{ii}=\sigma_i>0$ for $1\leq i\leq k$. The eigenvalues of $\Sigma^*\Sigma$ are σ_i^2. The vectors $\boldsymbol{u}_i$ for $k+1\leq i\leq m$ and $\boldsymbol{v}_i$ for $k+1\leq i\leq n$ are eigenvectors associated with the eigenvalue zero; the eigenvalues for $1\leq i\leq k$ are σ_i^2. The values of σ_i are called the singular values of the matrix $\boldsymbol{A}$. If $\boldsymbol{A}$ is real, then $\boldsymbol{U}$ and $\boldsymbol{V}$ are real, and hence orthogonal matrices. The value of the singular value decomposition comes when a process is represented by a linear transformation and the elements of $\boldsymbol{A}$, a_{ij}, are the contribution to an output i for a particular variable as input variable j. The input may be the size of a disturbance, and the output is the gain [1]. If the rank is less than n, not all the variables are independent and they cannot all be controlled. Furthermore, if the singular values are widely separated, the process is sensitive to small changes in the elements of the matrix and the process will be difficult to control.

1.2. Linear Algebraic Equations

Consider the $n \times n$ linear system

$$\begin{aligned} a_{11}\,x_1 + a_{12}\,x_2 + \ldots + a_{1n}\,x_n &= f_1 \\ a_{21}\,x_1 + a_{22}\,x_2 + \ldots + a_{2n}\,x_n &= f_2 \\ &\ldots \\ a_{n1}\,x_1 + a_{n2}\,x_2 + \ldots + a_{nn}\,x_n &= f_n \end{aligned}$$

In this equation $a_{11}, \ldots, a_{nn}$ are known parameters, $f_1, \ldots, f_n$ are known, and the unknowns are $x_1, \ldots, x_n$. The values of all unknowns that satisfy every equation must be found. This set of equations can be represented as follows:

$$\sum_{j=1}^{n} a_{ij}\,x_j = f_j \text{ or } \boldsymbol{A}\boldsymbol{x} = \boldsymbol{f}$$

The most efficient method for solving a set of linear algebraic equations is to perform a lower – upper (LU) decomposition of the corresponding matrix $\boldsymbol{A}$. This decomposition is essentially a Gaussian elimination, arranged for maximum efficiency [2, 3].

The LU decomposition writes the matrix as

$$\boldsymbol{A} = \boldsymbol{L}\boldsymbol{U}$$

The $\boldsymbol{U}$ is upper triangular; it has zero elements below the main diagonal and possibly nonzero values along the main diagonal and above it (see Fig. 1). The $\boldsymbol{L}$ is lower triangular. It has the value 1 in each element of the main diagonal, nonzero values below the diagonal, and zero values above the diagonal (see Fig. 1). The original problem can be solved in two steps:

$$\boldsymbol{L}\boldsymbol{y} = \boldsymbol{f}, \boldsymbol{U}\boldsymbol{x} = \boldsymbol{y} \text{ solves } \boldsymbol{A}\boldsymbol{x} = \boldsymbol{L}\boldsymbol{U}\boldsymbol{x} = \boldsymbol{f}$$

Each of these steps is straightforward because the matrices are upper triangular or lower triangular.

When f is changed, the last steps can be done without recomputing the LU decomposition. Thus, multiple right-hand sides can be computed efficiently. The number of multiplications and divisions necessary to solve for m right-hand sides is:

$$\text{Operation count } = \frac{1}{3}n^3 - \frac{1}{3}n + m\,n^2$$

The *determinant* is given by the product of the diagonal elements of $\boldsymbol{U}$. This should be calculated as the LU decomposition is performed.

Figure 1. Structure of $\boldsymbol{L}$ and $\boldsymbol{U}$ matrices

If the value of the determinant is a very large or very small number, it can be divided or multiplied by 10 to retain accuracy in the computer; the scale factor is then accumulated separately. The condition number κ can be defined in terms of the singular value decomposition as the ratio of the largest d_{ii} to the smallest d_{ii} (see above). It can also be expressed in terms of the norm of the matrix:

$$\kappa\,(A) = \|\boldsymbol{A}\|\|\boldsymbol{A}^{-1}\|$$

where the norm is defined as

$$\|\boldsymbol{A}\| \equiv \sup_{x \neq 0} \frac{\|\boldsymbol{A}\boldsymbol{x}\|}{\|\boldsymbol{x}\|} = \max_k \sum_{j=1}^{n} |a_{jk}|$$

If this number is infinite, the set of equations is singular. If the number is too large, the matrix is said to be ill-conditioned. Calculation of

the condition number can be lengthy so another criterion is also useful. Compute the ratio of the largest to the smallest pivot and make judgments on the ill-conditioning based on that.

When a matrix is ill-conditioned the LU decomposition must be performed by using pivoting (or the singular value decomposition described above). With pivoting, the order of the elimination is rearranged. At each stage, one looks for the largest element (in magnitude); the next stages if the elimination are on the row and column containing that largest element. The largest element can be obtained from only the diagonal entries (partial pivoting) or from all the remaining entries. If the matrix is nonsingular, Gaussian elimination (or LU decomposition) could fail if a zero value were to occur along the diagonal and were to be a pivot. With full pivoting, however, the Gaussian elimination (or LU decomposition) cannot fail because the matrix is nonsingular.

The *Cholesky decomposition* can be used for real, symmetric, positive definite matrices. This algorithm saves on storage (divide by about 2) and reduces the number of multiplications (divide by 2), but adds n square roots.

The linear equations are solved by

$$\boldsymbol{x} = \boldsymbol{A}^{-1}\boldsymbol{f}$$

Generally, the inverse is not used in this way because it requires three times more operations than solving with an LU decomposition. However, if an inverse is desired, it is calculated most efficiently by using the LU decomposition and then solving

$$\boldsymbol{A}\boldsymbol{x}^{(i)} = \boldsymbol{b}^{(i)}$$

$$b_j^{(i)} = \begin{cases} 0 & j \neq i \\ 1 & j = i \end{cases}$$

Then set

$$\boldsymbol{A}^{-1} = \left(\boldsymbol{x}^{(1)} | \boldsymbol{x}^{(2)} | \boldsymbol{x}^{(3)} | \cdots | \boldsymbol{x}^{(n)}\right)$$

Solutions of Special Matrices. Special matrices can be handled even more efficiently. A *tridiagonal matrix* is one with nonzero entries along the main diagonal, and one diagonal above and below the main one (see Fig. 2). The corresponding set of equations can then be written as

$$a_i x_{i-1} + b_i x_i + c_i x_{i+1} = d_i$$

The LU decomposition algorithm for solving this set is

$b'_1 = b_1$
for $k = 2, n$ do
$a'_k = \frac{a_k}{b'_{k-1}}$, $b'_k = b_k - \frac{a_k}{b'_{k-1}} c_{k-1}$
enddo
$d'_1 = d_1$
for $k = 2, n$ do
$d'_k = d_k - a'_k d'_{k-1}$
enddo
$x_n = d'_n / b'_n$
for $k = n-1, 1$do
$x_k = \frac{d'_k - c_k x_{k+1}}{b'_k}$
enddo

The number of multiplications and divisions for a problem with n unknowns and m right-hand sides is

$$\text{Operation count} = 2(n-1) + m(3n-2)$$

If

$$|b_i| > |a_i| + |c_i|$$

no pivoting is necessary. For solving two-point boundary value problems and partial differential equations this is often the case.

Figure 2. Structure of tridiagonal matrices

Sparse matrices are ones in which the majority of elements are zero. If the zero entries occur in special patterns, efficient techniques can be used to exploit the structure, as was done above for tridiagonal matrices, block tridiagonal

matrices, arrow matrices, etc. These structures typically arise from numerical analysis applied to solve differential equations. Other problems, such as modeling chemical processes, lead to sparse matrices but without such a neatly defined structure—just a lot of zeros in the matrix. For matrices such as these, special techniques must be employed: efficient codes are available [4]. These codes usually employ a symbolic factorization, which must be repeated only once for each structure of the matrix. Then an LU factorization is performed, followed by a solution step using the triangular matrices. The symbolic factorization step has significant overhead, but this is rendered small and insignificant if matrices with exactly the same structure are to be used over and over [5].

The efficiency of a technique for solving sets of linear equations obviously depends greatly on the arrangement of the equations and unknowns because an efficient arrangement can reduce the bandwidth, for example. Techniques for renumbering the equations and unknowns arising from elliptic partial differential equations are available for finite difference methods [6] and for finite element methods [7].

Solutions with Iterative Methods. Sets of linear equations can also be solved by using iterative methods; these methods have a rich historical background. Some of them are discussed in Chapter 8 and include Jacobi, Gauss – Seidel, and overrelaxation methods. As the speed of computers increases, direct methods become preferable for the general case, but for large three-dimensional problems iterative methods are often used.

The *conjugate gradient method* is an iterative method that can solve a set of *n* linear equations in *n* iterations. The method primarily requires multiplying a matrix by a vector, which can be done very efficiently on parallel computers: for sparse matrices this is a viable method. The original method was devised by Hestenes and Stiefel [8]; however, more recent implementations use a *preconditioned* conjugate gradient method because it converges faster, provided a good "preconditioner" can be found. The system of *n* linear equations

$$\boldsymbol{A}\boldsymbol{x} = \boldsymbol{f}$$

where $\boldsymbol{A}$ is symmetric and positive definite, is to be solved. A preconditioning matrix $\boldsymbol{M}$ is defined in such a way that the problem

$$\boldsymbol{M}\boldsymbol{t} = \boldsymbol{r}$$

is easy to solve exactly ($\boldsymbol{M}$ might be diagonal, for example). Then the preconditioned conjugate gradient method is

Guess $\boldsymbol{x}_0$

Calculate $\boldsymbol{r}_0 = \boldsymbol{f} - \boldsymbol{A}\boldsymbol{x}_0$

Solve $\boldsymbol{M}\,\boldsymbol{t}_0 = \boldsymbol{r}_0$, and set $\boldsymbol{p}_0 = \boldsymbol{t}_0$

for $k = 1, n$ (or until convergence)

$a_k = \frac{\boldsymbol{r}_k^{\mathrm{T}}\boldsymbol{t}_k}{\boldsymbol{p}_k^{\mathrm{T}}\boldsymbol{A}\boldsymbol{p}_k}$

$\boldsymbol{x}_{k+1} = \boldsymbol{x}_k + a_k\boldsymbol{p}_k$

$\boldsymbol{r}_{k+1} = \boldsymbol{r}_k - \boldsymbol{a}_k\boldsymbol{A}\boldsymbol{p}_k$

Solve $\boldsymbol{M}t_{k+1} = \boldsymbol{r}_{k+1}$

$b_k = \frac{\boldsymbol{r}_{k+1}^{\mathrm{T}}\boldsymbol{t}_{k+1}}{\boldsymbol{r}_k^{\mathrm{T}}\boldsymbol{t}_k}$

$\boldsymbol{p}_{k+1} = \boldsymbol{t}_{k+1} + b_k\boldsymbol{p}_k$

test for convergence

enddo

Note that the entire algorithm involves only matrix multiplications. The generalized minimal residual method (GMRES) is an iterative method that can be used for nonsymmetric systems and is based on a modified Gram – Schmidt orthonormalization. Additional information, including software for a variety of methods, is available [9 – 13].

In dimensional analysis if the dimensions of each physical variable P_j (there are *n* of them) are expressed in terms of fundamental measurement units m_j (such as time, length, mass; there are *m* of them):

$$[P_j] = m_1^{\alpha_{1j}} m_2^{\alpha_{2j}} \cdots m_m^{\alpha_{mj}}$$

then a matrix can be formed from the α_{ij}. If the rank of this matrix is *r*, $n - r$ independent dimensionless groups govern that phenomenon. In chemical reaction engineering the chemical reaction stoichiometry can be written as

$$\sum_{i=1}^{n} \alpha_{ij}\, C_i = 0,\ j = 1, 2, \ldots, m$$

where there are *n* species and *m* reactions. Then if a matrix is formed from the coefficients α_{ij}, which is an $n \times m$ matrix, and the rank of the matrix is *r*, there are *r* independent chemical reactions. The other $n - r$ reactions can be deduced from those *r* reactions.

1.3. Nonlinear Algebraic Equations

Consider a single nonlinear equation in one unknown,

$$f(x) = 0$$

In Microsoft Excel, roots are found by using Goal Seek or Solver. Assign one cell to be x, put the equation for $f(x)$ in another cell, and let Goal Seek or Solver find the value of x making the equation cell zero. In MATLAB, the process is similar except that a function (m-file) is defined and the command fzero('f',x0) provides the solution x, starting from the initial guess x_0.

Iterative methods applied to single equations include the *successive substitution* method

$$x^{k+1} = x^k + \beta f\left(x^k\right) \equiv g\left(x^k\right)$$

and the Newton – Raphson method.

$$x^{k+1} = x^k - \frac{f\left(x^k\right)}{\mathrm{d}f/\mathrm{d}x\left(x^k\right)}$$

The former method converges if the derivative of $g(x)$ is bounded [3]. The latter method

$$\left|\frac{\mathrm{d}g}{\mathrm{d}x}(x)\right| \leq \mu \text{ for } |x-\alpha| < h$$

is based on a Taylor series of the equation about the k-th iterate:

$$f\left(x^{k+1}\right) = f\left(x^k\right) + \frac{\mathrm{d}f}{\mathrm{d}x}\Big|_{x^k}\left(x^{k+1}-x^k\right) + \frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\Big|_{x^k}\frac{1}{2}\left(x^{k+1}-x^k\right)^2 + \cdots$$

The second and higher-order terms are neglected and $f\left(x^{k+1}\right) = 0$ to obtain the method.

$$\left|\frac{\mathrm{d}f}{\mathrm{d}x}\right|_{x^0} > 0,\ \left|x^1 - x^0\right| = \left|\frac{f\left(x^0\right)}{\mathrm{d}f/\mathrm{d}x\left(x^0\right)}\right|_{x^0} \leq b, \quad \text{and } \left|\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\right| \leq c$$

Convergence of the Newton–Raphson method depends on the properties of the first and second derivative of $f(x)$ [3, 14]. In practice the method may not converge unless the initial guess is good, or it may converge for some parameters and not others. Unfortunately, when the method is nonconvergent the results look as though a mistake occurred in the computer programming; distinguishing between these situations is difficult, so careful programming and testing are required. If the method converges the difference between successive iterates is something like 0.1, 0.01, 0.0001, 10^{-8}. The error (when it is known) goes the same way; the method is said to be quadratically convergent when it converges. If the derivative is difficult to calculate a numerical approximation may be used.

$$\frac{\mathrm{d}f}{\mathrm{d}x}\Big|_{x^k} = \frac{f\left(x^k+\varepsilon\right) - f\left(x^k\right)}{\varepsilon}$$

In the *secant method* the same formula is used as for the Newton – Raphson method, except that the derivative is approximated by using the values from the last two iterates:

$$\frac{\mathrm{d}f}{\mathrm{d}x}\Big|_{x^k} = \frac{f\left(x^k\right) - f\left(x^{k-1}\right)}{x^k - x^{k-1}}$$

This is equivalent to drawing a straight line through the last two iterate values on a plot of $f(x)$ versus x. The Newton – Raphson method is equivalent to drawing a straight line tangent to the curve at the last x. In the *method of false position* (or regula falsi), the secant method is used to obtain x^{k+1}, but the previous value is taken as either x^{k-1} or x^k. The choice is made so that the function evaluated for that choice has the opposite sign to $f\left(x^{k+1}\right)$. This method is slower than the secant method, but it is more robust and keeps the root between two points at all times. In all these methods, appropriate strategies are required for bounds on the function or when $\mathrm{d}f/\mathrm{d}x = 0$. *Brent's method* combines bracketing, bisection, and an inverse quadratic interpolation to provide a method that is fast and guaranteed to converge, if the root can be bracketed initially [15, p. 251].

In the *method of bisection*, if a root lies between x_1 and x_2 because $f(x_1) < 0$ and $f(x_2) > 0$, then the function is evaluated at the center, $x_c = 0.5(x_1 + x_2)$. If $f(x_c) > 0$, the root lies between x_1 and x_c. If $f(x_c) < 0$, the root lies between x_c and x_2. The process is then repeated. If $f(x_c) = 0$, the root is x_c. If $f(x_1) > 0$ and $f(x_2) > 0$, more than one root may exist between x_1 and x_2 (or no roots).

For systems of equations the Newton – Raphson method is widely used, especially for equations arising from the solution of differential equations.

$$f_i\left(\{x_j\}\right) = 0,\ 1 \leq i, j \leq n,$$
$$\text{where } \{x_j\} = (x_1, x_2, \ldots, x_n) = \boldsymbol{x}$$

Then, an expansion in several variables occurs:

$$\boldsymbol{f}_i\left(\boldsymbol{x}^{k+1}\right)=f_i\left(\boldsymbol{x}^k\right)+\sum_{j=1}^{n}\frac{\partial f_i}{\partial x_j}|_{\boldsymbol{x}^k}\left(x_j^{k+1}-x_j^k\right)+\cdots$$

The Jacobian matrix is defined as

$$\boldsymbol{J}_{ij}^k=\left.\frac{\partial f_i}{\partial x_j}\right|_{\boldsymbol{x}^k}$$

and the Newton – Raphson method is

$$\sum_{j=1}^{n}\boldsymbol{J}_{ij}^k\left(x^{k+1}-x^k\right)=-f_i\left(\boldsymbol{x}^k\right)$$

For convergence, the norm of the inverse of the Jacobian must be bounded, the norm of the function evaluated at the initial guess must be bounded, and the second derivative must be bounded [14, p. 115], [3, p. 12].

A review of the usefulness of solution methods for nonlinear equations is available [16]. This review concludes that the Newton – Raphson method may not be the most efficient. Broyden's method approximates the inverse to the Jacobian and is a good all-purpose method, but a good initial approximation to the Jacobian matrix is required. Furthermore, the rate of convergence deteriorates for large problems, for which the Newton – Raphson method is better. Brown's method [16] is very attractive, whereas Brent's is not worth the extra storage and computation. For large systems of equations, efficient software is available [11 – 13].

Homotopy methods can be used to ensure finding the solution when the problem is especially complicated. Suppose an attempt is made to solve $f(\boldsymbol{x}) = 0$, and it fails; however, $g(\boldsymbol{x}) = 0$ can be solved easily, where $g(\boldsymbol{x})$ is some function, perhaps a simplification of $f(\boldsymbol{x})$. Then, the two functions can be embedded in a homotopy by taking

$$\boldsymbol{h}(\boldsymbol{x},t)=t\,f(\boldsymbol{x})+(1-t)\,g(x)$$

In this equation, $\boldsymbol{h}$ can be a $n\times n$ matrix for problems involving n variables; then x is a vector of length n. Then $h(x, t) = 0$ can be solved for $t = 0$ and t gradually changes until at $t = 1$, $\boldsymbol{h}(\boldsymbol{x}, 1) = f(\boldsymbol{x})$. If the Jacobian of $\boldsymbol{h}$ with respect to x is nonsingular on the homotopy path (as t varies), the method is guaranteed to work. In classical methods, the interval from $t = 0$ to $t = 1$ is broken up into N subdivisions. Set $\Delta t = 1/N$ and solve for $t = 0$, which is easy by the choice of $g(x)$. Then set $t = \Delta t$ and use the Newton – Raphson method to solve for x. Since the initial guess is presumably pretty good, this has a high chance of being successful. That solution is then used as the initial guess for $t = 2\,\Delta t$ and the process is repeated by moving stepwise to $t = 1$. If the Newton – Raphson method does not converge, then Δt must be reduced and a new solution attempted.

Another way of using homotopy is to create an ordinary differential equation by differentiating the homotopy equation along the path (where $\boldsymbol{h} = 0$).

$$\frac{\mathrm{d}\boldsymbol{h}\left[\boldsymbol{x}(t),t\right]}{\mathrm{d}t}=\frac{\partial\boldsymbol{h}}{\partial\boldsymbol{x}}\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}+\frac{\partial\boldsymbol{h}}{\partial t}=0$$

This can be expressed as an ordinary differential equation for $x(t)$:

$$\frac{\partial\boldsymbol{h}}{\partial\boldsymbol{x}}\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}=-\frac{\partial\boldsymbol{h}}{\partial t}$$

If Euler's method is used to solve this equation, a value x^0 is used, and $\mathrm{d}x/\mathrm{d}t$ from the above equation is solved for. Then

$$\boldsymbol{x}^{1,0}=\boldsymbol{x}^0+\Delta t\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}$$

is used as the initial guess and the homotopy equation is solved for $\boldsymbol{x}^1$.

$$\frac{\partial\boldsymbol{h}}{\partial x}\left(\boldsymbol{x}^{1,k+1}-\boldsymbol{x}^{1,k}\right)=-\boldsymbol{h}\left(\boldsymbol{x}^{1,k},t\right)$$

Then t is increased by Δt and the process is repeated.

In arc-length parameterization, both x and t are considered parameterized by a parameter s, which is thought of as the arc length along a curve. Then the homotopy equation is written along with the arc-length equation.

$$\frac{\partial\boldsymbol{h}}{\partial\boldsymbol{x}}\frac{\mathrm{d}x}{\mathrm{d}\boldsymbol{s}}+\frac{\partial\boldsymbol{h}}{\partial t}\frac{\mathrm{d}t}{\mathrm{d}\boldsymbol{s}}=0$$

$$\frac{\mathrm{d}\boldsymbol{x}^{\mathrm{T}}}{\mathrm{d}\boldsymbol{s}}\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}+\left(\frac{\mathrm{d}t}{\mathrm{d}\boldsymbol{s}}\right)^2=1$$

The initial conditions are

$$\boldsymbol{x}(0)=\boldsymbol{x}^0$$
$$t(0)=0$$

The advantage of this approach is that it works even when the Jacobian of $\boldsymbol{h}$ becomes singular because the full matrix is rarely singular. Illustrations applied to chemical engineering are available [17]. Software to perform these computations is available (called LOCA) [18].

1.4. Linear Difference Equations

Difference equations arise in chemical engineering from staged operations, such as distillation or extraction, as well as from differential equations modeling adsorption and chemical reactors. The value of a variable in the n-th stage is noted by a subscript n. For example, if $y_{n,i}$ denotes the mole fraction of the i-th species in the vapor phase on the n-th stage of a distillation column, $x_{n,i}$ is the corresponding liquid mole fraction, R the reflux ratio (ratio of liquid returned to the column to product removed from the condenser), and $K_{n,i}$ the equilibrium constant, then the mass balances about the top of the column give

$$y_{n+1,i} = \frac{R}{R+1}x_{n,i}+\frac{1}{R+1}x_{0,i}$$

and the equilibrium equation gives

$$y_{n,i} = K_{n,i}x_{n,i}$$

If these are combined,

$$K_{n+1,i}x_{n+1,i} = \frac{R}{R+1}x_{n,i}+\frac{1}{R+1}x_{0,i}$$

is obtained, which is a linear difference equation. This particular problem is quite complicated, and the interested reader is referred to [19, Chap. 6]. However, the form of the difference equation is clear. Several examples are given here for solving difference equations. More complete information is available in [20].

An equation in the form

$$x_{n+1}-x_n=f_{n+1}$$

can be solved by

$$x_n = \sum_{i=1}^{n} f_i$$

Usually, difference equations are solved analytically only for linear problems. When the coefficients are constant and the equation is linear and homogeneous, a trial solution of the form

$$x_n = \varphi^n$$

is attempted; φ is raised to the power n. For example, the difference equation

$$cx_{n-1}+bx_n+ax_{n+1} = 0$$

coupled with the trial solution would lead to the equation

$$a\varphi^2+b\varphi+c = 0$$

This gives

$$\varphi_{1,2} = \frac{-b\pm\sqrt{b^2-4ac}}{2a}$$

and the solution to the difference equation is

$$x_n = A\varphi_1^n+B\varphi_2^n$$

where A and B are constants that must be specified by boundary conditions of some kind.

When the equation is nonhomogeneous, the solution is represented by the sum of a particular solution and a general solution to the homogeneous equation.

$$x_n = x_{n,P}+x_{n,H}$$

The general solution is the one found for the homogeneous equation, and the particular solution is any solution to the nonhomogeneous difference equation. This can be found by methods analogous to those used to solve differential equations: the method of undetermined coefficients and the method of variation of parameters. The last method applies to equations with variable coefficients, too. For a problem such as

$$x_{n+1}-f_nx_n = 0$$
$$x_0 = c$$

the general solution is

$$x_n=c\prod_{i=1}^{n} f_{i-1}$$

This can then be used in the method of variation of parameters to solve the equation

$$x_{n+1}-f_nx_n = g_n$$

1.5. Eigenvalues

The $n\times n$ matrix $\boldsymbol{A}$ has n eigenvalues λ_i, $i = 1, \ldots, n$, which satisfy

$$\det(\boldsymbol{A}-\lambda_i\boldsymbol{I}) = 0$$

If this equation is expanded, it can be represented as

$$P_n(\lambda) = (-\lambda)^n+a_1(-\lambda)^{n-1}+a_2(-\lambda)^{n-2}+\cdots +a_{n-1}(-\lambda)+a_n = 0$$

If the matrix $\boldsymbol{A}$ has real entries then a_i are real numbers, and the eigenvalues either are real

numbers or occur in pairs as complex numbers with their complex conjugates (for definition of complex numbers, see Chap. 3). The Hamilton – Cayley theorem [19, p. 127] states that the matrix $\boldsymbol{A}$ satisfies its own characteristic equation.

$$P_n(\boldsymbol{A}) = (-\boldsymbol{A})^n + a_1(-\boldsymbol{A})^{n-1} + a_2(-\boldsymbol{A})^{n-2} + \cdots + a_{n-1}(-\boldsymbol{A}) + a_n \boldsymbol{I} = 0$$

A laborious way to find the eigenvalues of a matrix is to solve the n-th order polynomial for the λ_i—far too time consuming. Instead the matrix is transformed into another form whose eigenvalues are easier to find. In the *Givens method* and the *Housholder method* the matrix is transformed into the tridiagonal form; then, in a fixed number of calculations the eigenvalues can be found [15]. The Givens method requires $4\,n^3/3$ operations to transform a real symmetric matrix to tridiagonal form, whereas the Householder method requires half that number [14]. Once the tridiagonal form is found, a Sturm sequence is applied to determine the eigenvalues. These methods are especially useful when only a few eigenvalues of the matrix are desired.

If all the eigenvalues are needed, the $\boldsymbol{Q}\,\boldsymbol{R}$ algorithm is preferred [21].

The eigenvalues of a certain tridiagonal matrix can be found analytically. If $\boldsymbol{A}$ is a tridiagonal matrix with

$$a_{ii} = p, a_{i,i+1} = q, a_{i+1,i} = r, qr > 0$$

then the eigenvalues of $\boldsymbol{A}$ are [22]

$$\lambda_i = p + 2(qr)^{1/2}\cos\frac{i\pi}{n+1} \quad i = 1,2,\ldots,n$$

This result is useful when finite difference methods are applied to the diffusion equation.

2. Approximation and Integration

2.1. Introduction

Two types of problems arise frequently:

1) A *function* is known exactly at a set of points and an interpolating function is desired. The interpolant may be exact at the set of points, or it may be a "best fit" in some sense. Alternatively it may be desired to represent a function in some other way.
2) *Experimental data* must be fit with a mathematical model. The data have experimental error, so some uncertainty exists. The parameters in the model as well as the uncertainty in the determination of those parameters is desired.

These problems are addressed in this chapter. Section 2.2 gives the properties of polynomials defined over the whole domain and Section 2.3 of polynomials defined on segments of the domain. In Section 2.4, quadrature methods are given for evaluating an integral. Least-squares methods for parameter estimation for both linear and nonlinear models are given in Sections 2.5. Fourier transforms to represent discrete data are described in Section 2.7. The chapter closes with extensions to two-dimensional representations.

2.2. Global Polynomial Approximation

A *global* polynomial $P_m(x)$ is defined over the entire region of space

$$P_m(x) = \sum_{j=0}^{m} c_j x^j$$

This polynomial is of degree m (highest power is x^m) and order $m + 1$ ($m + 1$ parameters $\{c_j\}$). If a set of $m + 1$ points is given,

$$y_1 = f(x_1), y_2 = f(x_2), \ldots, y_{m+1} = f(x_{m+1})$$

then Lagrange's formula yields a polynomial of degree m that goes through the $m + 1$ points:

$$P_m(x) = \frac{(x-x_2)(x-x_3)\cdots(x-x_{m+1})}{(x_1-x_2)(x_1-x_3)\cdots(x_1-x_{m+1})} y_1 + \frac{(x-x_1)(x-x_3)\cdots(x-x_{m+1})}{(x_2-x_1)(x_2-x_3)\cdots(x_2-x_{m+1})} y_2 + \cdots + \frac{(x-x_1)(x-x_2)\cdots(x-x_m)}{(x_{m+1}-x_1)(x_{m+1}-x_2)\cdots(x_{m+1}-x_m)} y_{m+1}$$

Note that each coefficient of y_j is a polynomial of degree m that vanishes at the points $\{x_j\}$ (except for one value of j) and takes the value of 1.0 at that point, i.e.,

$$P_m(x_j) = y_j \quad j = 1, 2, \ldots, m+1$$

If the function $f(x)$ is known, the error in the approximation is [23]

$$|\text{error}(x)| \le \frac{|x_{m+1} - x_1|^{m+1}}{(m+1)!} \max_{x_1 \le x \le x_{m+1}} \left| f^{(m+1)}(x) \right|$$

The evaluation of $P_m(x)$ at a point other than the defining points can be made with Neville's algorithm [15]. Let P_1 be the value at x of the unique function passing through the point (x_1, y_1); i.e., $P_1 = y_1$. Let P_{12} be the value at x of the unique polynomial passing through the points x_1 and x_2. Likewise, $P_{ijk\ldots r}$ is the unique polynomial passing through the points $x_i, x_j, x_k, \ldots, x_r$. The following scheme is used:

$$\begin{array}{llllll} x_1 & y_1 = P_1 & & & \\ & & P_{12} & & \\ x_2 & y_2 = P_2 & & P_{123} & \\ & & P_{23} & & P_{1234} \\ x_3 & y_3 = P_3 & & P_{234} & \\ & & P_{34} & & \\ x_4 & y_4 = P_4 & & & \end{array}$$

These entries are defined by using

$$P_{i(i+1)\cdots(i+m)} = \frac{(x-x_{i+m})P_{i(i+1)\cdots(i+m-1)} + (x_i - x)P_{(i+1)(i+2)\cdots(i+m)}}{x_i - x_{i+m}}$$

Consider P_{1234}: the terms on the right-hand side of the equation involve P_{123} and P_{234}. The "parents," P_{123} and P_{234}, already agree at points 2 and 3. Here $i = 1$, $m = 3$; thus, the parents agree at $x_{i+1}, \ldots, x_{i+m-1}$ already. The formula makes $P_{i(i+1)\ldots(i+m)}$ agree with the function at the additional points x_{i+m} and x_i. Thus, $P_{i(i+1)\ldots(i+m)}$ agrees with the function at all the points $\{x_i, x_{i+1}, \ldots, x_{i+m}\}$.

Orthogonal Polynomials. Another form of the polynomials is obtained by defining them so that they are orthogonal. It is required that $P_m(x)$ be orthogonal to $P_k(x)$ for all $k = 0, \ldots, m-1$.

$$\int_a^b W(x) P_k(x) P_m(x)\,\mathrm{d}x = 0$$

$$k = 0,1,2,\ldots,m-1$$

The orthogonality includes a nonnegative weight function, $W(x) \geq 0$ for all $a \leq x \leq b$. This procedure specifies the set of polynomials to within multiplicative constants, which can be set either by requiring the leading coefficient to be one or by requiring the norm to be one.

$$\int_a^b W(x) P_m^2(x)\,\mathrm{d}x = 1$$

The polynomial $P_m(x)$ has m roots in the closed interval a to b.

The polynomial

$$p(x) = c_0 P_0(x) + c_1 P_1(x) + \cdots c_m P_m(x)$$

minimizes

$$I = \int_a^b W(x)\,[f(x) - p(x)]^2\,\mathrm{d}x$$

when

$$c_j = \frac{\int_a^b W(x)\, f(x) P_j(x)\,\mathrm{d}x}{W_j},$$

$$W_j = \int_a^b W(x) P_j^2(x)\,\mathrm{d}x$$

Note that each c_j is independent of m, the number of terms retained in the series. The minimum value of I is

$$I_{\min} = \int_a^b W(x)\, f^2(x)\,\mathrm{d}x - \sum_{j=0}^{m} W_j c_j^2$$

Such functions are useful for continuous data, i.e., when $f(x)$ is known for all x.

Typical orthogonal polynomials are given in Table 1. Chebyshev polynomials are used in spectral methods (see Chap. 8). The last two rows of Table 1 are widely used in the orthogonal collocation method in chemical engineering.

Table 1. Orthogonal polynomials [15, 23]

a	b	$W(x)$	Name	Recursion relation
-1	1	1	Legendre	$(i+1)P_{i+1} = (2i+1)xP_i - iP_{i-1}$
-1	1	$\frac{1}{\sqrt{1-x^2}}$	Chebyshev	$T_{i+1} = 2xT_i - T_{i-1}$
0	1	$x^{q-1}(1-x)^{p-q}$	Jacobi (p, q)	
$-\infty$	∞	e^{-x^2}	Hermite	$H_{i+1} = 2xH_i - 2iH_{i-1}$
0	∞	$x^c\,\mathrm{e}^{-x}$	Laguerre (c)	$(i+1)L_{i+1}^c = (-x+2i+c+1)L_i^c - (i+c)L_{i-1}^c$
0	1	1	shifted Legendre	
0	1	1	shifted Legendre, function of x^2	

The last entry (the shifted Legendre polynomial as a function of x^2) is defined by

$$\int_0^1 W\left(x^2\right) P_k\left(x^2\right) P_m\left(x^2\right) x^{a-1} \mathrm{d}x = 0$$
$$k = 0,1,\ldots,m-1$$

where $a = 1$ is for planar, $a = 2$ for cylindrical, and $a = 3$ for spherical geometry. These functions are useful if the solution can be proved to be an even function of x.

Rational Polynomials. Rational polynomials are ratios of polynomials. A rational polynomial $R_{i(i+1)\ldots(i+m)}$ passing through $m + 1$ points

$$y_i = f\left(x_i\right),\ i = 1,\ldots,m+1$$

is

$$R_{i(i+1)\cdots(i+m)} = \frac{P_\mu(x)}{Q_\nu(x)} = \frac{p_0+p_1x+\cdots+p_\mu x^\mu}{q_0+q_1x+\cdots+q_\nu x^\nu},$$
$$m+1 = \mu+\nu+1$$

An alternative condition is to make the rational polynomial agree with the first $m + 1$ terms in the power series, giving a Padé approximation, i.e.,

$$\frac{\mathrm{d}^k R_{i(i+1)\cdots(i+m)}}{\mathrm{d}x^k} = \frac{\mathrm{d}^k f(x)}{\mathrm{d}x^k} \quad k = 0,\ldots,m$$

The Bulirsch – Stoer recursion algorithm can be used to evaluate the polynomial:

$$R_{i(i+1)\cdots(i+m)} = R_{(i+1)\cdots(i+m)}$$
$$+\frac{R_{(i+1)\cdots(i+m)}-R_{i(i+1)\cdots(i+m-1)}}{\mathrm{Den}}$$
$$\mathrm{Den} = \left(\frac{x-x_i}{x-x_{i+m}}\right)$$
$$\left(1-\frac{R_{(i+1)\cdots(i+m)}R_{i(i+1)\cdots(i+m-1)}}{R_{(i+1)\cdots(i+m)}-R_{(i+1)\cdots(i+m-1)}}\right)-1$$

Rational polynomials are useful for approximating functions with poles and singularities, which occur in Laplace transforms (see Section 4.2).

Fourier series are discussed in Section 4.1. Representation by sums of exponentials is also possible [24].

In summary, for discrete data, Legendre polynomials and rational polynomials are used. For continuous data a variety of orthogonal polynomials and rational polynomials are used. When the number of conditions (discrete data points) exceeds the number of parameters, then see Section 2.5.

2.3. Piecewise Approximation

Piecewise approximations can be developed from difference formulas [3]. Consider a case in which the data points are equally spaced

$$x_{n+1}-x_n = \Delta x$$
$$y_n = y\left(x_n\right)$$

forward differences are defined by

$$\Delta y_n = y_{n+1}-y_n$$
$$\Delta^2 y_n = \Delta y_{n+1}-\Delta y_n = y_{n+2}-2y_{n+1}+y_n$$

Then, a new variable is defined

$$\alpha = \frac{x_\alpha - x_0}{\Delta x}$$

and the finite interpolation formula through the points $y_0, y_1, \ldots, y_n$ is written as follows:

$$y_\alpha = y_0+\alpha\Delta y_0+\frac{\alpha(\alpha-1)}{2!}\Delta^2 y_0+\cdots+ \frac{\alpha(\alpha-1)\cdots(\alpha-n+1)}{n!}\Delta^n y_0 \tag{1}$$

Keeping only the first two terms gives a straight line through $(x_0, y_0) - (x_1, y_1)$; keeping the first three terms gives a quadratic function of position going through those points plus (x_2, y_2). The value $\alpha = 0$ gives $x = x_0$; $\alpha = 1$ gives $x = x_1$, etc.

Backward differences are defined by

$$\nabla y_n = y_n - y_{n-1}$$
$$\nabla^2 y_n = \nabla y_n - \nabla y_{n-1} = y_n - 2y_{n-1} + y_{n-2}$$

The interpolation polynomial of order n through the points $y_0, y_{-1}, y_{-2}, \ldots$ is

$$y_\alpha = y_0+\alpha\nabla y_0+\frac{\alpha(\alpha+1)}{2!}\nabla^2 y_0+\cdots+ \frac{\alpha(\alpha+1)\cdots(\alpha+n-1)}{n!}\nabla^n y_0$$

The value $\alpha = 0$ gives $x = x_0$; $\alpha = -1$ gives $x = x_{-1}$. Alternatively, the interpolation polynomial of order n through the points $y_1, y_0, y_{-1}, \ldots$ is

$$y_\alpha = y_1+(\alpha-1)\nabla y_1+\frac{\alpha(\alpha-1)}{2!}\nabla^2 y_1+\cdots+ \frac{(\alpha-1)\alpha(\alpha+1)\cdots(\alpha+n-2)}{n!}\nabla^n y_1$$

Now $\alpha = 1$ gives $x = x_1$; $\alpha = 0$ gives $x = x_0$.

The *finite element method* can be used for piecewise approximations [3]. In the finite element method the domain $a \le x \le b$ is divided

into elements as shown in Figure 3. Each function $N_i(x)$ is zero at all nodes except x_i; $N_i(x_i) = 1$. Thus, the approximation is

$$y(x) = \sum_{i=1}^{NT} c_i N_i(x) = \sum_{i=1}^{NT} y(x_i) N_i(x)$$

where $c_i = y(x_i)$. For convenience, the trial functions are defined within an element by using new coordinates:

$$u = \frac{x - x_i}{\Delta x_i}$$

The Δx_i need not be the same from element to element. The trial functions are defined as $N_i(x)$ (Fig. 3 A) in the global coordinate system and $N_I(u)$ (Fig. 3 B) in the local coordinate system (which also requires specification of the element). For $x_i < x < x_{i+1}$

Figure 3. Galerkin finite element method – linear functions
A) Global numbering system; B) Local numbering system

$$y(x) = \sum_{i=1}^{NT} c_i N_i(x) = c_i N_i(x) + c_{i+1} N_{i+1}(x)$$

because all the other trial functions are zero there. Thus

$$y(x) = c_i N_{I=1}(u) + c_{i+1} N_{I=2}(u),$$

$$x_i < x < x_{i+1},\ 0 < u < 1$$

Then

$$N_{I=1} = 1 - u,\ N_{I=2} = u$$

and the expansion is rewritten as

$$y(x) = \sum_{I=1}^{2} c_I^e N_I(u) \tag{2}$$

x in e-th element and $c_i = c_I^e$ within the element e. Thus, given a set of points (x_i, y_i), a finite element approximation can be made to go through them.

Quadratic approximations can also be used within the element (see Fig. 4). Now the trial functions are

Figure 4. Finite elements approximation – quadratic elements
A) Global numbering system; B) Local numbering system

$$\begin{aligned} N_{I=1} &= 2(u-1)\left(u-\tfrac{1}{2}\right) \\ N_{I=2} &= 4u(1-u) \\ N_{I=3} &= 2u\left(u-\tfrac{1}{2}\right) \end{aligned} \tag{3}$$

The approximation going through an odd number of points (x_i, y_i) is then

$$y(x) = \sum_{I=1}^{3} c_I^e N_I(u) \quad x \text{ in } e\text{-th element}$$

with $c_I^e = y(x_i)$, $i = (e-1)2 + I$
in the e-th element

Hermite cubic polynomials can also be used; these are continuous and have continuous first derivatives at the element boundaries [3].

Splines. Splines are functions that match given values at the points $x_1, \ldots, x_{NT}$, shown in Figure 5, and have continuous derivatives up to some order at the knots, or the points $x_2, \ldots, x_{NT-1}$. *Cubic splines* are most common. In this case the function is represented by a cubic polynomial within each interval and has continuous first and second derivatives at the knots.

Figure 5. Finite elements for cubic splines
A) Notation for spline knots. B) Notation for one element

Consider the points shown in Figure 5 A. The notation for each interval is shown in Figure 5 B. Within each interval the function is represented as a cubic polynomial.

$$C_i(x) = a_{0i} + a_{1i}x + a_{2i}x^2 + a_{3i}x^3$$

The interpolating function takes on specified values at the knots.

$$C_{i-1}(x_i) = C_i(x_i) = f(x_i)$$

Given the set of values $\{x_i, f(x_i)\}$, the objective is to pass a smooth curve through those points, and the curve should have continuous first and second derivatives at the knots.

$$C'_{i-1}(x_i) = C'_i(x_i)$$

$$C''_{i-1}(x_i) = C''_i(x_i)$$

The formulas for the cubic spline are derived as follows for one region. Since the function is a cubic function the third derivative is constant and the second derivative is linear in x. This is written as

$$C''_i(x) = C''_i(x_i) + \left[C''_i(x_{i+1}) - C''_i(x_i)\right]\frac{x - x_i}{\Delta x_i}$$

and integrated once to give

$$C'_i(x) = C'_i(x_i) + C''_i(x_i)(x - x_i) + \left[C''_i(x_{i+1}) - C''_i(x_i)\right]\frac{(x - x_i)^2}{2\Delta x_i}$$

and once more to give

$$C_i(x) = C_i(x_i) + C'_i(x_i)(x - x_i) + C''_i(x_i)\frac{(x - x_i)^2}{2} + \left[C''_i(x_{i+1}) - C''_i(x_i)\right]\frac{(x - x_i)^3}{6\Delta x_i}$$

Now

$$y_i = C_i(x_i), y'_i = C'_i(x_i), y''_i = C''_i(x_i)$$

is defined so that

$$C_i(x) = y_i + y'_i(x - x_i) + \tfrac{1}{2}y''_i(x - x_i)^2 + \frac{1}{6\Delta x_i}\left(y''_{i+1} - y''_i\right)(x - x_i)^3$$

A number of algebraic steps make the interpolation easy. These formulas are written for the i-th element as well as the $i - 1$-th element. Then the continuity conditions are applied for the first and second derivatives, and the values y'_i and y'_{i-1} are eliminated [15]. The result is

$$y''_{i-1}\Delta x_{i-1} + y''_i\, 2(\Delta x_{i-1} + \Delta x_i) + y''_{i+1}\Delta x_i = -6\left(\frac{y_i - y_{i-1}}{\Delta x_{i-1}} - \frac{y_{i+1} - y_i}{\Delta x_i}\right)$$

This is a tridiagonal system for the set of $\{y''_i\}$ in terms of the set of $\{y_i\}$. Since the continuity conditions apply only for $i = 2, \ldots, NT - 1$, only $NT - 2$ conditions exist for the NT values of y''_i. Two additional conditions are needed, and these are usually taken as the value of the second derivative at each end of the domain, y''_1, y''_{NT}. If these values are zero, the *natural cubic splines* are obtained; they can also be set to achieve some other purpose, such as making the first derivative match some desired condition at the two ends. With these values taken as zero, in the natural cubic spline, an $NT - 2$ system of tridiagonal equations exists, which is easily solved. Once the second derivatives are known at each of the knots, the first derivatives are given by

$$y'_i = \frac{y_{i+1} - y_i}{\Delta x_i} - y''_i\frac{\Delta x_i}{3} - y''_{i+1}\frac{\Delta x_i}{6}$$

The function itself is then known within each element.

Orthogonal Collocation on Finite Elements. In the method of orthogonal collocation on finite elements the solution is expanded in a polynomial of order $NP = NCOL + 2$ within each element [3]. The choice $NCOL = 1$ corresponds to using quadratic polynomials, whereas $NCOL = 2$ gives cubic polynomials. The notation is shown in Figure 6. Set the function to a known value at the two endpoints

$$y_1 = y(x_1)$$

$$y_{NT} = y(x_{NT})$$

and then at the $NCOL$ interior points to each element

Figure 6. Notation for orthogonal collocation on finite elements
• Residual condition; ■ Boundary conditions; | Element boundary, continuity
NE = total no. of elements.
NT = (*NCOL* + 1) *NE* + 1

$$y_i^e = y_i = y(x_i), i = (NCOL+1)e+I$$

The actual points x_i are taken as the roots of the orthogonal polynomial.

$$P_{NCOL}(u) = 0 \text{ gives } u_1, u_2, \ldots, u_{NCOL}$$

and then

$$x_i = x_{(e)} + \Delta x_e u_I \equiv x_I^e$$

The first derivatives must be continuous at the element boundaries:

$$\frac{\mathrm{d}y}{\mathrm{d}x}\Big|_{x=x_{(2)-}} = \frac{\mathrm{d}y}{\mathrm{d}x}\Big|_{x=x_{(2)+}}$$

Within each element the interpolation is a polynomial of degree *NCOL* + 1. Overall the function is continuous with continuous first derivatives. With the choice *NCOL* = 2, the same approximation is achieved as with Hermite cubic polynomials.

2.4. Quadrature

To calculate the value of an integral, the function can be approximated by using each of the methods described in Section 2.3. Using the first three terms in Equation 1 gives

$$\int_{x_0}^{x_0+h} y(x)\,\mathrm{d}x = \int_0^1 y_\alpha h \mathrm{d}\alpha$$
$$= \frac{h}{2}(y_0+y_1) - \frac{1}{12}h^3 y_0''(\xi), x_0 \le \xi \le x_0+h$$

This corresponds to passing a straight line through the points (x_0, y_0), (x_1, y_1) and integrating under the interpolant. For equally spaced points at $a = x_0$, $a + \Delta x = x_1$, $a + 2\,\Delta x = x_2$, . . . , $a + N\,\Delta x = x_N$, $a + (N + 1)\,\Delta x = b = x_{n+1}$, the trapezoid rule is obtained.

Trapezoid Rule.

$$\int_a^b y(x)\,\mathrm{d}x = \frac{h}{2}(y_0+2y_1+2y_2+\cdots+2y_N$$
$$+y_{N+1}) + O(h^3)$$

The first five terms in Equation 1 are retained and integrated over two intervals.

$$\int_{x_0}^{x_0+2h} y(x)\,\mathrm{d}x = \int_0^2 y_\alpha h \mathrm{d}\alpha = \frac{h}{3}(y_0+4y_1+y_2)$$
$$-\frac{h^5}{90} y_0^{(\mathrm{IV})}(\xi), x_0 \le \xi \le x_0+2h$$

This corresponds to passing a quadratic function through three points and integrating. For an even number of intervals and an odd number of points, 2 *N* + 1, with $a = x_0$, $a + \Delta x = x_1$, $a + 2\,\Delta x = x_2$, . . . , $a + 2\,N\,\Delta x = b$, Simpson's rule is obtained.

Simpson's Rule.

$$\int_a^b y(x)\,\mathrm{d}x = \frac{h}{3}(y_0+4y_1+2y_2+4y_3+2y_4$$
$$+\cdots+2y_{2N-1}+4y_{2N}+y_{2N+1}) + O(h^5)$$

Within each pair of intervals the interpolant is continuous with continuous derivatives, but only the function is continuous from one pair to another.

If the *finite element representation* is used (Eq. 2), the integral is

$$\int_{x_i}^{x_{i+1}} y(x)\,\mathrm{d}x = \int_0^1 \sum_{I=1}^{2} c_I^e N_I(u)(x_{i+1}-x_i)\,\mathrm{d}u$$
$$= \Delta x_i \sum_{I=1}^{2} c_I^e \int_0^1 N_I(u)\,\mathrm{d}u = \Delta x_i \left(c_1^e \tfrac{1}{2} + c_2^e \tfrac{1}{2}\right)$$
$$= \tfrac{\Delta x_i}{2}(y_i + y_{i+1})$$

Since $c_1^e = y_i$ and $c_2^e = y_{i+1}$, the result is the same as the trapezoid rule. These formulas can be added together to give *linear elements*:

$$\int_a^b y(x)\,\mathrm{d}x = \sum\nolimits_e \frac{\Delta x_e}{2}(y_1^e + y_2^e)$$

If the *quadratic* expansion is used (Eq. 3), the endpoints of the element are x_i and x_{i+2}, and x_{i+1} is the midpoint, here assumed to be equally spaced between the ends of the element:

$$\int_{x_i}^{x_{i+2}} y(x)\,\mathrm{d}x = \int_0^1 \sum_{I=1}^{3} c_I^e N_I(u)(x_{i+2}-x_i)\,\mathrm{d}u$$
$$= \Delta x_i \sum_{I=1}^{3} c_I^e \int_0^1 N_I(u)\,\mathrm{d}u$$
$$= \Delta x_e \left(c_1^e \tfrac{1}{6} + c_2^e \tfrac{2}{3} + c_3^e \tfrac{1}{6}\right)$$

For many elements, with different Δx^e, *quadratic elements:*

$$\int_a^b y(x) = \sum\nolimits_e \frac{\Delta x_e}{6}(y_1^e + 4y_2^e + y_3^e)$$

If the element sizes are all the same this gives Simpson's rule.

For cubic splines the quadrature rule within one element is

$$\int_{x_i}^{x_{i+1}} C_i(x)\,\mathrm{d}x = \tfrac{1}{2}\Delta x_i (y_i + y_{i+1}) - \tfrac{1}{24}\Delta x_i^3 \left(y_i'' + y_{i+1}''\right)$$

For the entire interval the quadrature formula is

$$\int_{x_1}^{x_{NT}} y(x)\,\mathrm{d}x = \tfrac{1}{2}\sum_{i=1}^{NT-1} \Delta x_i (y_i + y_{i+1}) - \tfrac{1}{24}\sum_{i=1}^{NT-1} \Delta x_i^3 (y_i'' + y_{i+1}'')$$

with $y_1'' = 0$, $y''_{NT} = 0$ for natural cubic splines.

When orthogonal polynomials are used, as in Equation 1, the m roots to $P_m(x) = 0$ are chosen as quadrature points and called points $\{x_j\}$. Then the quadrature is *Gaussian:*

$$\int_0^1 y(x)\,\mathrm{d}x = \sum_{j=1}^{m} W_j y(x_j)$$

The quadrature is exact when y is a polynomial of degree $2m - 1$ in x. The m weights and m Gauss points result in $2m$ parameters, chosen to exactly represent a polynomial of degree $2m - 1$, which has $2m$ parameters. The Gauss points and weights are given in Table 2. The weights can be defined with $W(x)$ in the integrand as well.

Table 2. Gaussian quadrature points and weights *

N	x_i	W_i
1	0.5000000000	0.6666666667
2	0.2113248654	0.5000000000
	0.7886751346	0.5000000000
3	0.1127016654	0.2777777778

	0.5000000000	0.2844444444
	0.7692346551	0.2393143353
	0.9530899230	0.1184634425

* For a given N the quadrature points $x_2, x_3, \ldots, x_{NP-1}$ are given above. $x_1 = 0$, $x_{NP} = 1$. For $N = 1$, $W_1 = W_3 = 1/6$ and for $N \geq 2$, $W_1 = W_{NP} = 0$.

For orthogonal collocation on finite elements the quadrature formula is

$$\int_0^1 y(x)\,\mathrm{d}x = \sum\nolimits_e \Delta x_e \sum_{j=1}^{NP} W_j y(x_j^e)$$

Each special polynomial has its own quadrature formula. For example, Gauss – Legendre polynomials give the quadrature formula

$$\int_0^\infty e^{-x} y(x)\,\mathrm{d}x = \sum_{i=1}^{n} W_i y(x_i)$$

(points and weights are available in mathematical tables) [23].

For Gauss – Hermite polynomials the quadrature formula is

$$\int_{-\infty}^{\infty} e^{-x^2} y(x)\,\mathrm{d}x = \sum_{i=1}^{n} W_i y(x_i)$$

(points and weights are available in mathematical tables) [23].

Romberg's method uses extrapolation techniques to improve the answer [15]. If I_1 is the value of the integral obtained by using interval size $h = \Delta x$, I_2 the value of I obtained by using interval size $h/2$, and I_0 the true value of I, then the error in a method is approximately h^m, or

$$I_1 \approx I_0 + ch^m$$

$$I_2 \approx I_0 + c\left(\frac{h}{2}\right)^m$$

Replacing the $\approx$ by an equality (an approximation) and solving for c and I_0 give

$$I_0 = \frac{2^m I_2 - I_1}{2^m - 1}$$

This process can also be used to obtain $I_1, I_2, \ldots$, by halving h each time, calculating new estimates from each pair, and calling them $J_1, J_2, \ldots$ (i.e., in the formula above, I_0 is replaced with J_1). The formulas are reapplied for each pair of J's to obtain $K_1, K_2, \ldots$. The process continues until the required tolerance is obtained.

I_1	I_2	I_3	I_4
	J_1	J_2	J_3
		K_1	K_2
			L_1

Romberg's method is most useful for a low-order method (small m) because significant improvement is then possible.

When the integrand has singularities, a variety of techniques can be tried. The integral may be divided into one part that can be integrated analytically near the singularity and another part that is integrated numerically. Sometimes a change of argument allows analytical integration. Series expansion might be helpful, too. When the domain is infinite, Gauss – Legendre or Gauss – Hermite quadrature can be used. Also a transformation can be made [15]. For example, let $u = 1/x$ and then

$$\int_a^b f(x)\,\mathrm{d}x = \int_{1/b}^{1/a} \frac{1}{u^2} f\left(\frac{1}{u}\right)\mathrm{d}u \quad a, b > 0$$

2.5. Least Squares

When fitting experimental data to a mathematical model, it is necessary to recognize that the experimental measurements contain error; the goal is to find the set of parameters in the model that best represents the experimental data. Reference [23] gives a complete treatment relating the least-squares procedure to maximum likelihood.

In a least-squares parameter estimation, it is desired to find parameters that minimize the sum of squares of the deviation between the experimental data and the theoretical equation

$$\chi^2 = \sum_{i=1}^{N} \left[\frac{y_i - y(x_i; a_1, a_2, \ldots, a_M)}{\sigma_i}\right]^2$$

where y_i is the i-th experimental data point for the value x_i, $y(x_i; a_1, a_2, \ldots, a_M)$ the theoretical equation at x_i, σ_i the standard deviation of the i-th measurement, and the parameters $\{a_1, a_2, \ldots, a_M\}$ are to be determined to minimize χ^2. The simplification is made here that the standard deviations are all the same. Thus, we minimize the variance of the curve fit.

$$\sigma^2 = \sum_{i=1}^{N} \frac{[y_i - y(x_i; a_1, a_2, \ldots, a_M)]^2}{N}$$

Linear Least Squares. When the model is a straight line, one is minimizing

$$\chi^2 = \sum_{i=1}^{N} [y_i - a - bx_i]^2$$

The linear correlation coefficient r is defined by

$$r = \frac{\sum_{i=1}^{N} (x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum_{i=1}^{N} (x_i - \overline{x})^2}\sqrt{\sum_{i=1}^{N} (y_i - \overline{y})^2}}$$

and

$$\chi^2 = (1 - r^2) \sum_{i=1}^{N} [y_i - \overline{y}]^2$$

where $\overline{y}$ is the average of y_i values. Values of r near 1 indicate a positive correlation; r near -1 means a negative correlation, and r near zero means no correlation. These parameters are easily found by using standard programs, such as Microsoft Excel.

Polynomial Regression. In polynomial regression, one expands the function in a polynomial in x.

$$y(x) = \sum_{j=1}^{M} a_j x^{j-1}$$

The parameters are easily determined using computer software. In Microsoft Excel, the data is put into columns A and B and the graph is created as for a linear curve fit. Then add a trendline and choose the degree of polynomial desired.

Multiple Regression. In multiple regression, any set of functions can be used, not just polynomials.

$$y(x) = \sum_{j=1}^{M} a_j f_j(x)$$

where the set of functions $\{f_j(x)\}$ is known and specified. Note that the unknown parameters $\{a_j\}$ enter the equation linearly. In this case, the spreadsheet can be expanded to have a column for x, and then successive columns for $f_j(x)$. In Microsoft Excel, choose Regression under Tools/Data Analysis, and complete the form. In addition to the actual correlation, one gets the expected variance of the unknowns, which allows one to assess how accurately they were determined.

Nonlinear Regression. In nonlinear regression, the same procedure is followed except that an optimization routine must be used to find the minimum χ^2. See Chapter 10.

2.6. Fourier Transforms of Discrete Data [15]

Suppose a signal $y(t)$ is sampled at equal intervals

$$y_n = y(n\Delta), n = \ldots, -2, -1, 0, 1, 2, \ldots$$

$\Delta =$ sampling rate

(e.g., number of samples per second)

The Fourier transform and inverse transform are

$$Y(\omega) = \int_{-\infty}^{\infty} y(t)\, e^{\mathrm{i}\omega t} \mathrm{d}t$$

$$y(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} Y(\omega)\, e^{-\mathrm{i}\omega t} \mathrm{d}\omega$$

(For definition of i, see Chap. 3.) The Nyquist critical frequency or critical angular frequency is

$$f_c = \frac{1}{2\Delta}, \omega_c = \frac{\pi}{\Delta}$$

If a function $y(t)$ is bandwidth limited to frequencies smaller than f_c, i.e.,

$$Y(\omega) = 0 \text{ for } \omega > \omega_c$$

then the function is completely determined by its samples y_n. Thus, the entire information content of a signal can be recorded by sampling at a rate $\Delta^{-1} = 2f_c$. If the function is not bandwidth limited, then aliasing occurs. Once a sample rate Δ is chosen, information corresponding to frequencies greater than f_c is simply aliased into that range. The way to detect this in a Fourier transform is to see if the transform approaches zero at $\pm f_c$; if not, aliasing has occurred and a higher sampling rate is needed.

Next, for N samples, where N is even

$$y_k = y(t_k),\ t_k = k\Delta,\ k = 0, 1, 2, \ldots, N-1$$

and the sampling rate is Δ; with only N values $\{y_k\}$ the complete Fourier transform $Y(\omega)$ cannot be determined. Calculate the value $Y(\omega_n)$ at the discrete points

$$\omega_n = \frac{2\pi n}{N\Delta}, n = -\frac{N}{2}, \ldots, 0, \ldots, \frac{N}{2}$$

$$Y_n = \sum_{k=0}^{N-1} y_k \mathrm{e}^{2\pi \mathrm{i} kn/N}$$

$$Y(\omega_n) = \Delta Y_n$$

The discrete inverse Fourier transform is

$$y_k = \frac{1}{N} \sum_{k=0}^{N-1} Y_n \mathrm{e}^{-2\pi \mathrm{i} kn/N}$$

The *fast Fourier transform* (*FFT*) is used to calculate the Fourier transform as well as the inverse Fourier transform. A discrete Fourier transform of length N can be written as the sum of two discrete Fourier transforms, each of length $N/2$, and each of these transforms is separated into two halves, each half as long. This continues until only one component is left. For this reason, N is taken as a power of 2, $N = 2^p$.

The vector $\{y_j\}$ is filled with zeroes, if need be, to make $N = 2^p$ for some p. For the computer program, see [15, p. 381]. The standard

Fourier transform takes N^2 operations to calculate, whereas the fast Fourier transform takes only $N \log_2 N$. For large N the difference is significant; at $N = 100$ it is a factor of 15, but for $N = 1000$ it is a factor of 100.

The discrete Fourier transform can also be used for *differentiating* a function; this is used in the spectral method for solving differential equations. Consider a grid of equidistant points:

$$x_n = n\Delta x, n = 0,1,2,\ldots, 2N-1, \Delta x = \frac{L}{2N}$$

the solution is known at each of these grid points $\{Y(x_n)\}$. First, the Fourier transform is taken:

$$y_k = \frac{1}{2N}\sum_{n=0}^{2N-1} Y(x_n)\,\mathrm{e}^{-2\mathrm{i}k\pi x_n/L}$$

The inverse transformation is

$$Y(x) = \frac{1}{L}\sum_{k=-N}^{N} y_k \mathrm{e}^{2\mathrm{i}k\pi x/L}$$

which is differentiated to obtain

$$\frac{\mathrm{d}Y}{\mathrm{d}x} = \frac{1}{L}\sum_{k=-N}^{N} y_k \frac{2\pi\mathrm{i}k}{L}\mathrm{e}^{2\mathrm{i}k\pi x/L}$$

Thus, at the grid points

$$\left.\frac{\mathrm{d}Y}{\mathrm{d}x}\right|_n = \frac{1}{L}\sum_{k=-N}^{N} y_k \frac{2\pi\mathrm{i}k}{L}\mathrm{e}^{2\mathrm{i}k\pi x_n/L}$$

The process works as follows. From the solution at all grid points the Fourier transform is obtained by using FFT $\{y_k\}$. This is multiplied by $2\pi\,\mathrm{i}\,k/L$ to obtain the Fourier transform of the derivative:

$$y'_k = y_k \frac{2\pi\mathrm{i}k}{L}$$

The inverse Fourier transform is then taken by using FFT, to give the value of the derivative at each of the grid points:

$$\left.\frac{\mathrm{d}Y}{\mathrm{d}x}\right|_n = \frac{1}{L}\sum_{k=-N}^{N} y'_k \mathrm{e}^{2\mathrm{i}k\pi x_n/L}$$

Any nonlinear term can be treated in the same way: evaluate it in real space at N points and take the Fourier transform. After processing using this transform to get the transform of a new function, take the inverse transform to obtain the new function at N points. This is what is done in direct numerical simulation of turbulence (DNS).

2.7. Two-Dimensional Interpolation and Quadrature

Bicubic splines can be used to interpolate a set of values on a regular array, $f(x_i, y_j)$. Suppose NX points occur in the x direction and NY points occur in the y direction. Press et al. [15] suggest computing NY different cubic splines of size NX along lines of constant y, for example, and storing the derivative information. To obtain the value of f at some point x, y, evaluate each of these splines for that x. Then do one spline of size NY in the y direction, doing both the determination and the evaluation.

Multidimensional integrals can also be broken down into one-dimensional integrals. For example,

$$\int_a^b \int_{f_1(x)}^{f_2(x)} z(x,y)\,\mathrm{d}x\mathrm{d}y = \int_a^b G(x)\,\mathrm{d}x;$$

$$G(x) = \int_{f_1(x)}^{f_2(x)} z(x,y)\,\mathrm{d}x$$

3. Complex Variables [25 – 31]

3.1. Introduction to the Complex Plane

A complex number is an ordered pair of real numbers, x and y, that is written as

$$z = x + \mathrm{i}y$$

The variable i is the imaginary unit which has the property

$$\mathrm{i}^2 = -1$$

The real and imaginary parts of a complex number are often referred to:

$$\mathrm{Re}\,(z) = x, \mathrm{Im}\,(z) = y$$

A complex number can also be represented graphically in the complex plane, where the real part of the complex number is the abscissa and the imaginary part of the complex number is the ordinate (see Fig. 7).

Another representation of a complex number is the *polar form*, where r is the magnitude and θ is the argument.

$$r = |x + \mathrm{i}\,y| = \sqrt{x^2 + y^2},\ \theta = \arg(x + \mathrm{i}\,y)$$

Figure 7. The complex plane

Write

$$z = x + \mathrm{i}\, y = r\,(\cos\theta + \mathrm{i}\sin\theta)$$

so that

$$x = r\cos\theta, y = r\sin\theta$$

and

$$\theta = \arctan\frac{y}{x}$$

Since the arctangent repeats itself in multiples of π rather than $2\,\pi$, the argument must be defined carefully. For example, the θ given above could also be the argument of $-\,(x + \mathrm{i}\, y)$. The function $z = \cos\theta + \mathrm{i}\sin\theta$ obeys $|z| = |\cos\theta + \mathrm{i}\sin\theta| = 1$.

The rules of equality, addition, and multiplication are

$$z_1 = x_1 + \mathrm{i}\, y_1, z_2 = x_2 + \mathrm{i}\, y_2$$

Equality :
$z_1 = z_2$ if and only if $x_1 = x_2$ and $y_1 = y_2$
Addition :
$z_1 + z_2 = (x_1 + x_2) + \mathrm{i}\,(y_1 + y_2)$
Multiplication :
$z_1 z_2 = (x_1 x_2 - y_1 y_2) + \mathrm{i}\,(x_1 y_2 + x_2 y_1)$

The last rule can be remembered by using the standard rules for multiplication, keeping the imaginary parts separate, and using $\mathrm{i}^2 = -\,1$. In the complex plane, addition is illustrated in Figure 8. In polar form, multiplication is

$$z_1 z_2 = r_1 r_2\,[\cos(\theta_1 + \theta_2) + \mathrm{i}\sin(\theta_1 + \theta_2)]$$

The magnitude of $z_1 + z_2$ is bounded by

$$|z_1 \pm z_2| \le |z_1| + |z_2| \text{ and } |z_1| - |z_2| \le |z_1 \pm z_2|$$

as can be seen in Figure 8. The magnitude and arguments in multiplication obey

$$|z_1 z_2| = |z_1|\,|z_2|\,, \arg(z_1 z_2) = \arg z_1 + \arg z_2$$

The *complex conjugate* is $z^* = x - \mathrm{i}\, y$ when $z = x + \mathrm{i}\, y$ and $|z^*| = |z|$, $\arg z^* = -\arg z$

Figure 8. Addition in the complex plane

For complex conjugates then

$$z^*\, z = |z|^2$$

The reciprocal is

$$\frac{1}{z} = \frac{z^*}{|z|^2} = \frac{1}{r}\,(\cos\theta - \mathrm{i}\sin\theta)\,, \arg\left(\frac{1}{z}\right) = -\arg z$$

Then

$$\frac{z_1}{z_2} = \frac{x_1 + \mathrm{i}\, y_1}{x_2 + \mathrm{i}\, y_2} = (x_1 + \mathrm{i}\, y_1)\,\frac{x_2 - \mathrm{i}\, y_2}{x_2^2 + y_2^2}$$
$$= \frac{x_1 x_2 + y_1 y_2}{x_2^2 + y_2^2} + \mathrm{i}\,\frac{x_2 y_1 - x_1 y_2}{x_2^2 + y_2^2}$$

and

$$\frac{z_1}{z_2} = \frac{r_1}{r_2}\,[\cos(\theta_1 - \theta_2) + \mathrm{i}\sin(\theta_1 - \theta_2)]$$

3.2. Elementary Functions

Properties of elementary functions of complex variables are discussed here [32]. When the polar form is used, the argument must be specified because the same physical angle can be achieved with arguments differing by $2\,\pi$. A complex number taken to a real power obeys

$$u = z^n,\ |z^n| = |z|^n, \arg\,(z^n) = n\arg z\,(\mathrm{mod}\,2\pi)$$

$$u = z^n = r^n\,(\cos n\theta + \mathrm{i}\sin n\theta)$$

Roots of a complex number are complicated by careful accounting of the argument

$z = w^{1/n}$ with $w = R(\cos\Theta + \mathrm{i}\sin\Theta)$, $0 \le \Theta \le 2\pi$

then

$$z_k = R^{1/n}\{\cos\left[\frac{\Theta}{n} + (k-1)\frac{2\pi}{n}\right]$$

$$+\mathrm{i}\sin\left[\frac{\Theta}{n} + (k-1)\frac{2\pi}{n}\right]\}$$

such that

$(z_k)^n = w$ for every k

$$z = r(\cos\theta + \mathrm{i}\sin\theta)$$
$$r^n = R, n\theta = \Theta \pmod{2\pi}$$

The exponential function is

$$e^z = \mathrm{e}^x(\cos y + \mathrm{i}\sin y)$$

Thus,

$$z = r(\cos\theta + \mathrm{i}\sin\theta)$$

can be written

$$z = r\mathrm{e}^{\mathrm{i}\theta}$$

and

$$|\mathrm{e}^z| = \mathrm{e}^x, \arg \mathrm{e}^z = y \pmod{2\pi}$$

The exponential obeys

$\mathrm{e}^z \neq 0$ for every finite z

and is periodic with period 2π:

$$e^{z+2\pi\,\mathrm{i}} = \mathrm{e}^z$$

Trigonometric functions can be defined by using

$e^{iy} = \cos y + \mathrm{i}\sin y$, and $\mathrm{e}^{-\mathrm{i}y} = \cos y - \mathrm{i}\sin y$

Thus,

$$\cos y = \frac{\mathrm{e}^{\mathrm{i}\,y} + \mathrm{e}^{-\mathrm{i}\,y}}{2} = \cosh \mathrm{i}\,y$$

$$\sin y = \frac{\mathrm{e}^{\mathrm{i}\,y} - \mathrm{e}^{-\mathrm{i}\,y}}{2\mathrm{i}} = -\mathrm{i}\sinh \mathrm{i}\,y$$

The second equation follows from the definitions

$$\cosh z \equiv \frac{\mathrm{e}^z + \mathrm{e}^{-z}}{2},\ \sinh z \equiv \frac{\mathrm{e}^z - \mathrm{e}^{-z}}{2}$$

The remaining hyperbolic functions are

$$\tanh z \equiv \frac{\sinh z}{\cosh z}, \coth z \equiv \frac{1}{\tanh z}$$

$$\mathrm{sech}\, z \equiv \frac{1}{\cosh z}, \mathrm{csch}\, z \equiv \frac{1}{\sinh z}$$

The circular functions with complex arguments are defined

$$\cos z = \frac{\mathrm{e}^{\mathrm{i}\,z} + \mathrm{e}^{-\mathrm{i}\,z}}{2}, \sin z = \frac{\mathrm{e}^{\mathrm{i}\,z} - \mathrm{e}^{-\mathrm{i}\,z}}{2},$$

$$\tan z = \frac{\sin z}{\cos z}$$

and satisfy

$$\sin(-z) = -\sin z, \cos(-z) = \cos z$$

$$\sin(\mathrm{i}\,z) = \mathrm{i}\sinh z, \cos(\mathrm{i}\,z) = -\cosh z$$

All trigonometric identities for real, circular functions with real arguments can be extended without change to complex functions of complex arguments. For example,

$$\sin^2 z + \cos^2 z = 1,$$

$$\sin(z_1 + z_2) = \sin z_1 \cos z_2 + \cos z_1 \sin z_2$$

The same is true of hyperbolic functions. The absolute boundaries of $\sin z$ and $\cos z$ are not bounded for all z.

Trigonometric identities can be defined by using

$$e^{i\theta} = \cos\theta + \mathrm{i}\sin\theta$$

For example,

$$\mathrm{e}^{\mathrm{i}(\alpha+\beta)} = \cos(\alpha+\beta) + \mathrm{i}\sin(\alpha+\beta)$$

$$= \mathrm{e}^{\mathrm{i}\alpha}\mathrm{e}^{\mathrm{i}\beta} = (\cos\alpha + \mathrm{i}\sin\alpha)$$
$$(\cos\beta + \mathrm{i}\sin\beta)$$
$$= \cos\alpha\cos\beta - \sin\alpha\sin\beta$$
$$+\mathrm{i}\ (\cos\alpha\sin\beta + \cos\beta\sin\alpha)$$

Equating real and imaginary parts gives

$$\cos(\alpha+\beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta$$

$$\sin(\alpha+\beta) = \cos\alpha\sin\beta + \cos\beta\sin\alpha$$

The logarithm is defined as

$$\ln z = \ln|z| + \mathrm{i}\arg z$$

and the various determinations differ by multiples of 2π i. Then,

$$\mathrm{e}^{\ln z} = z$$

$$\ln(\mathrm{e}^z) - z \equiv 0 \pmod{2\pi\mathrm{i}}$$

Also,

$$\ln(z_1 z_2) - \ln z_1 - \ln z_2 \equiv 0 \pmod{2\pi\mathrm{i}}$$

is always true, but

$$\ln(z_1 z_2) = \ln z_1 + \ln z_2$$

holds only for some determinations of the logarithms. The principal determination of the argument can be defined as $-\pi < \arg \le \pi$.

3.3. Analytic Functions of a Complex Variable

Let $f(z)$ be a single-valued continuous function of z in a domain D. The function $f(z)$ is differentiable at the point z_0 in D if

$$\lim_{h\to 0}\frac{f(z_0+h)-f(z_0)}{h}$$

exists as a finite (complex) number and is independent of the direction in which h tends to zero. The limit is called the derivative, $f'(z_0)$. The derivative now can be calculated with h approaching zero in the complex plane, i.e., anywhere in a circular region about z_0. The function $f(z)$ is differentiable in D if it is differentiable at all points of D; then $f(z)$ is said to be an analytic function of z in D. Also, $f(z)$ is analytic at z_0 if it is analytic in some ε neighborhood of z_0. The word analytic is sometimes replaced by holomorphic or regular.

The *Cauchy – Riemann equations* can be used to decide if a function is analytic. Set

$$f(z) = f(x+\mathrm{i}\,y) = u(x,y) + \mathrm{i}\,v(x,y)$$

Theorem [30, p. 51]. Suppose that $f(z)$ is defined and continuous in some neighborhood of $z = z_0$. A necessary condition for the existence of $f'(z_0)$ is that $u(x, y)$ and $v(x, y)$ have first-order partials and that the Cauchy – Riemann conditions (see below) hold.

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \text{ and } \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x} \text{ at } z_0$$

Theorem [30, p. 61]. The function $f(z)$ is analytic in a domain D if and only if u and v are continuously differentiable and satisfy the Cauchy – Riemann conditions there.

If $f_1(z)$ and $f_2(z)$ are analytic in domain D, then $\alpha_1 f_1(z) + \alpha_2 f_2(z)$ is analytic in D for any (complex) constants α_1, α_2.

$$f_1(z) + f_2(z) \text{ is analytic in D}$$

$$f_1(z)/f_2(z) \text{ is analytic in D except where } f_2(z) = 0$$

An analytic function of an analytic function is analytic. If $f(z)$ is analytic, $f'(z) \neq 0$ in D, $f(z_1) \neq f(z_2)$ for $z_1 \neq z_2$, then the inverse function $g(w)$ is also analytic and

$$g'(w) = \frac{1}{f'(z)} \text{ where } w = f(z),$$

$$g(w) = g[f(z)] = z$$

Analyticity implies continuity but the converse is not true: $z^* = x - \mathrm{i}\,y$ is continuous but, because the Cauchy – Riemann conditions are not satisfied, it is not analytic. An entire function is one that is analytic for all finite values of z. Every polynomial is an entire function. Because the polynomials are analytic, a ratio of polynomials is analytic except when the denominator vanishes. The function $f(z) = |z^2|$ is continuous for all z but satisfies the Cauchy – Riemann conditions only at $z = 0$. Hence, $f'(z)$ exists only at the origin, and $|z|^2$ is nowhere analytic. The function $f(z) = 1/z$ is analytic except at $z = 0$. Its derivative is $-1/z^2$, where $z \neq 0$. If $\ln z = \ln|z| + \mathrm{i}\arg z$ in the cut domain $-\pi < \arg z \leq \pi$, then $f(z) = 1/\ln z$ is analytic in the same cut domain, except at $z = 1$, where $\log z = 0$. Because e^z is analytic and $\pm\,\mathrm{i}\,z$ are analytic, $\mathrm{e}^{\pm \mathrm{i} z}$ is analytic and linear combinations are analytic. Thus, the sine and cosine and hyperbolic sine and cosine are analytic. The other functions are analytic except when the denominator vanishes.

The derivatives of the elementary functions are

$$\frac{\mathrm{d}}{\mathrm{d}z}\mathrm{e}^z = \mathrm{e}^z,\ \frac{\mathrm{d}}{\mathrm{d}z}z^n = n\,z^{n-1}$$

$$\frac{\mathrm{d}}{\mathrm{d}z}(\ln z) = \frac{1}{z},\ \frac{\mathrm{d}}{\mathrm{d}z}\sin z = \cos z,$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\cos z = -\sin z$$

In addition,

$$\frac{\mathrm{d}}{\mathrm{d}z}(f\,g) = f\frac{\mathrm{d}g}{\mathrm{d}z} + g\frac{\mathrm{d}f}{\mathrm{d}z}$$

$$\frac{\mathrm{d}}{\mathrm{d}z}f[g(z)] = \frac{\mathrm{d}f}{\mathrm{d}g}\frac{\mathrm{d}g}{\mathrm{d}z}$$

$$\frac{\mathrm{d}}{\mathrm{d}z}\sin w = \cos w\frac{\mathrm{d}w}{\mathrm{d}z},\ \frac{\mathrm{d}}{\mathrm{d}z}\cos w = -\sin w\frac{\mathrm{d}w}{\mathrm{d}z}$$

Define $z^a = \mathrm{e}^{a\ln z}$ for complex constant a. If the determination is $-\pi < \arg z \leq \pi$, then z^a is analytic on the complex plane with a cut on the negative real axis. If a is an integer n, then $\mathrm{e}^{2\pi i n} = 1$ and z^n has the same limits approaching the cut from either side. The function can be made continuous across the cut and the function is analytic there, too. If $a = 1/n$ where n is an integer, then

$$z^{1/n} = \mathrm{e}^{(\ln z)/n} = |z|^{1/n}\mathrm{e}^{\mathrm{i}(\arg z)/n}$$

So $w = z^{1/n}$ has n values, depending on the choice of argument.

Laplace Equation. If $f(z)$ is analytic, where

$$f(z) = u(x,y) + \mathrm{i}\, v(x,y)$$

the Cauchy – Riemann equations are satisfied. Differentiating the Cauchy – Riemann equations gives the Laplace equation:

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial^2 v}{\partial x \partial y} = \frac{\partial^2 v}{\partial y \partial x} = -\frac{\partial^2 u}{\partial y^2} \text{ or}$$

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0$$

Similarly,

$$\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = 0$$

Thus, general solutions to the Laplace equation can be obtained from analytic functions [30, p. 60]. For example,

$$\ln \frac{1}{|z - z_0|}$$

is analytic so that a solution to the Laplace equation is

$$\ln \left[(x-a)^2 + (y-b)^2\right]^{-1/2}$$

A solution to the Laplace equation is called a harmonic function. A function is harmonic if, and only if, it is the real part of an analytic function. The imaginary part is also harmonic. Given any harmonic function u, a conjugate harmonic function v can be constructed such that $f = u + \mathrm{i}\, v$ is locally analytic [30, p. 290].

Maximum Principle. If $f(z)$ is analytic in a domain D and continuous in the set consisting of D and its boundary C, and if $|f(z)| \leq M$ on C, then $|f(z)| < M$ in D unless $f(z)$ is a constant [30, p. 134].

3.4. Integration in the Complex Plane

Let C be a rectifiable curve in the complex plane

$$C: z = z(t), 0 \leq t \leq 1$$

where $z(t)$ is a continuous function of bounded variation; C is oriented such that $z_1 = z(t_1)$ precedes the point $z_2 = z(t_2)$ on C if and only if $t_1 < t_2$. Define

$$\int_C f(z)\,\mathrm{d}z = \int_0^1 f[z(t)]\,\mathrm{d}z(t)$$

The integral is linear with respect to the integrand:

$$\int_C [\alpha_1 f_1(z) + \alpha_2 f_2(z)]\,\mathrm{d}z$$
$$= \alpha_1 \int_C f_1(z)\,\mathrm{d}z + \alpha_2 \int_C f_2(z)\,\mathrm{d}z$$

The integral is additive with respect to the path. Let curve C_2 begin where curve C_1 ends and $C_1 + C_2$ be the path of C_1 followed by C_2. Then,

$$\int_{C_1+C_2} f(z)\,\mathrm{d}z = \int_{C_1} f(z)\,\mathrm{d}z + \int_{C_2} f(z)\,\mathrm{d}z$$

Reversing the orientation of the path replaces the integral by its negative:

$$\int_{-C} f(z)\,\mathrm{d}z = -\int_C f(z)\,\mathrm{d}z$$

If the path of integration consists of a finite number of arcs along which $z(t)$ has a continuous derivative, then

$$\int_C f(z)\,\mathrm{d}z = \int_0^1 f[z(t)]\,z'(t)\,\mathrm{d}t$$

Also if $s(t)$ is the arc length on C and $l(C)$ is the length of C

$$\left|\int_C f(z)\,\mathrm{d}z\right| \leq \max_{z \in C} |f(z)|\, l(C)$$

and

$$\left|\int_C f(z)\,\mathrm{d}z\right| \leq \int_C |f(z)|\,|\mathrm{d}z| = \int_0^1 |f[z(t)]|\,\mathrm{d}s(t)$$

Cauchy's Theorem [25, 30, p. 111]. Suppose $f(z)$ is an analytic function in a domain D and C is a simple, closed, rectifiable curve in D such that $f(z)$ is analytic inside and on C. Then

$$\oint_C f(z)\,\mathrm{d}z = 0 \tag{4}$$

If D is simply connected, then Equation 4 holds for every simple, closed, rectifiable curve C in D. If D is simply connected and if a and b are any two points in D, then

$$\int_a^b f(z)\,\mathrm{d}z$$

is independent of the rectifiable path joining a and b in D.

Cauchy's Integral. If C is a closed contour such that $f(z)$ is analytic inside and on C, z_0 is a point inside C, and z traverses C in the counterclockwise direction,

$$f(z_0) = \frac{1}{2\pi \mathrm{i}} \oint_C \frac{f(z)}{z-z_0} \mathrm{d}z$$

$$f'(z_0) = \frac{1}{2\pi \mathrm{i}} \oint_C \frac{f(z)}{(z-z_0)^2} \mathrm{d}z$$

Under further restriction on the domain [30, p. 127],

$$f^{(m)}(z_0) = \frac{m!}{2\pi \mathrm{i}} \oint_C \frac{f(z)}{(z-z_0)^{m+1}} \mathrm{d}z$$

Power Series. If $f(z)$ is analytic interior to a circle $|z - z_0| < r_0$, then at each point inside the circle the series

$$f(z) = f(z_0) + \sum_{n=1}^{\infty} \frac{f^{(n)}(z_0)}{n!} (z-z_0)^n$$

converges to $f(z)$. This result follows from Cauchy's integral. As an example, e^z is an entire function (analytic everywhere) so that the MacLaurin series

$$\mathrm{e}^z = 1 + \sum_{n=1}^{\infty} \frac{z^n}{n!}$$

represents the function for all z.

Another result of Cauchy's integral formula is that if $f(z)$ is analytic in an annulus R, $r_1 < |z - z_0| < r_2$, it is represented in R by the Laurent series

$$f(z) = \sum_{n=-\infty}^{\infty} A_n (z-z_0)^n, r_1 < |z-z_0| \leq r_2$$

where

$$A_n = \frac{1}{2\pi \mathrm{i}} \int_C \frac{f(z)}{(z-z_0)^{n+1}} \mathrm{d}z,$$

$$n = 0, \pm 1, \pm 2, \ldots,$$

and C is a closed curve counterclockwise in R.

Singular Points and Residues [33, p. 159, 30, p. 180]. If a function in analytic in every neighborhood of z_0, but not at z_0 itself, then z_0 is called an isolated singular point of the function. About an isolated singular point, the function can be represented by a Laurent series.

$$f(z) = \cdots + \frac{A_{-2}}{(z-z_0)^2} + \frac{A_{-1}}{z-z_0} + A_0 + A_1 (z-z_0) + \cdots 0 < |z-z_0| \leq r_0 \tag{5}$$

In particular,

$$A_{-1} = \frac{1}{2\pi \mathrm{i}} \oint_C f(z) \mathrm{d}z$$

where the curve C is a closed, counterclockwise curve containing z_0 and is within the neighborhood where $f(z)$ is analytic. The complex number A_{-1} is the residue of $f(z)$ at the isolated singular point z_0; $2\pi \mathrm{i} A_{-1}$ is the value of the integral in the positive direction around a path containing no other singular points.

If $f(z)$ is defined and analytic in the exterior $|z - z_0| > \mathrm{R}$ of a circle, and if

$$v(\zeta) = f\left(z_0 + \frac{1}{\zeta}\right) \text{ obtained by } \zeta = \frac{1}{z-z_0}$$

has a removable singularity at $\zeta = 0$, $f(z)$ is analytic at infinity. It can then be represented by a Laurent series with nonpositive powers of $z - z_0$.

If C is a closed curve within which and on which $f(z)$ is analytic except for a finite number of singular points $z_1, z_2, \ldots, z_n$ interior to the region bounded by C, then the residue theorem states

$$\oint_C f(z) \mathrm{d}z = 2\pi \mathrm{i} (\varrho_1 + \varrho_2 + \cdots \varrho_n)$$

where ϱ_n denotes the residue of $f(z)$ at z_n.

The series of negative powers in Equation 5 is called the principal part of $f(z)$. If the principal part has an infinite number of nonvanishing terms, the point z_0 is an essential singularity. If $A_{-m} \neq 0$, $A_{-n} = 0$ for all $m < n$, then z_0 is called a pole of order m. It is a simple pole if $m = 1$. In such a case,

$$f(z) = \frac{A_{-1}}{z-z_0} + \sum_{n=0}^{\infty} A_n (z-z_0)^n$$

If a function is not analytic at z_0 but can be made so by assigning a suitable value, then z_0 is a removable singular point.

When $f(z)$ has a pole of order m at z_0,

$$\varphi(z) = (z-z_0)^m f(z), 0 < |z-z_0| < r_0$$

has a removable singularity at z_0. If $\varphi(z_0) = A_{-m}$, then $\varphi(z)$ is analytic at z_0. For a simple pole,

$$A_{-1} = \varphi(z_0) = \lim_{z \to z_0} (z-z_0) f(z)$$

Also $|f(z)| \to \infty$ as $z \to z_0$ when z_0 is a pole. Let the function $p(z)$ and $q(z)$ be analytic at z_0, where $p(z_0) \neq 0$. Then

$$f(z) = \frac{p(z)}{q(z)}$$

has a simple pole at z_0 if, and only if, $q(z_0) = 0$ and $q'(z_0) \neq 0$. The residue of $f(z)$ at the simple pole is

$$A_{-1} = \frac{p(z_0)}{q'(z_0)}$$

If $q^{(i-1)}(z_0) = 0$, i = 1, . . . , m, then z_0 is a pole of $f(z)$ of order m.

Branch [33, p. 163]. A branch of a multiple-valued function $f(z)$ is a single-valued function that is analytic in some region and whose value at each point there coincides with the value of $f(z)$ at the point. A branch cut is a boundary that is needed to define the branch in the greatest possible region. The function $f(z)$ is singular along a branch cut, and the singularity is not isolated. For example,

$$z^{1/2} = f_1(z) = \sqrt{r}\left(\cos\frac{\theta}{2} + \mathrm{i}\sin\frac{\theta}{2}\right)$$

$$-\pi < \theta < \pi,\ r > 0$$

is double valued along the negative real axis. The function tends to $\sqrt{r}\mathrm{i}$ when $\theta \to \pi$ and to $-\sqrt{r}\mathrm{i}$ when $\theta \to -\pi$; the function has no limit as $z \to -r$ $(r > 0)$. The ray $\theta = \pi$ is a branch cut.

Analytic Continuation [33, p. 165]. If $f_1(z)$ is analytic in a domain D_1 and domain D contains D_1, then an analytic function $f(z)$ may exist that equals $f_1(z)$ in D_1. This function is the analytic continuation of $f_1(z)$ onto D, and it is unique. For example,

$$f_1(z) = \sum_{n=0}^{\infty} z^n,\ |z| < 1$$

is analytic in the domain $D_1 : |z| < 1$. The series diverges for other z. Yet the function is the MacLaurin series in the domain

$$f_1(z) = \frac{1}{1-z},\ |z| < 1$$

Thus,

$$f_1(z) = \frac{1}{1-z}$$

is the analytic continuation onto the entire z plane except for $z = 1$.

An extension of the Cauchy integral formula is useful with Laplace transforms. Let the curve C be a straight line parallel to the imaginary axis and z_0 be any point to the right of that (see Fig. 9). A function $f(z)$ is of order z^k as $|z| \to \infty$ if positive numbers M and r_0 exist such that

$$|z^{-k} f(z)| < M \text{ when } |z| > r_0, \text{ i.e.,}$$

$$|f(z)| < M|z|^k \text{ for } |z| \text{ sufficiently large}$$

Figure 9. Integration in the complex plane

Theorem [33, p. 167]. Let $f(z)$ be analytic when $R(z) \geq \gamma$ and $O(z^{-k})$ as $|z| \to \infty$ in that half-plane, where γ and k are real constants and $k > 0$. Then for any z_0 such that $R(z_0) > \gamma$

$$f(z_0) = -\frac{1}{2\pi\mathrm{i}} \lim_{\beta\to\infty} \int_{\gamma-\mathrm{i}\beta}^{\gamma+\mathrm{i}\beta} \frac{f(z)}{z-z_0}\mathrm{d}z,$$

i.e., integration takes place along the line $x = \gamma$.

3.5. Other Results

Theorem [32, p. 84]. Let $P(z)$ be a polynomial of degree n having the zeroes $z_1, z_2, \ldots, z_n$ and let π be the least convex polygon containing the zeroes. Then $P'(z)$ cannot vanish anywhere in the exterior of π.

If a polynomial has real coefficients, the roots are either real or form pairs of complex conjugate numbers.

The radius of convergence R of the Taylor series of $f(z)$ about z_0 is equal to the distance from z_0 to the nearest singularity of $f(z)$.

Conformal Mapping. Let $u(x, y)$ be a harmonic function. Introduce the coordinate transformation

$$x = \hat{x}(\xi, \eta), \; y = \hat{y}(\xi, \eta)$$

It is desired that

$$U(\xi, \eta) = u[\hat{x}(\xi, \eta), \hat{y}(\xi, \eta)]$$

be a harmonic function of ξ and η.

Theorem [30, p. 284]. The transformation

$$z = f(\zeta) \tag{6}$$

takes all harmonic functions of x and y into harmonic functions of ξ and η if and only if either $f(\zeta)$ or $f^*(\zeta)$ is an analytic function of $\zeta = \xi + \mathrm{i}\,\eta$.

Equation 6 is a restriction on the transformation which ensures that

$$\text{if } \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0 \text{ then } \frac{\partial^2 U}{\partial \zeta^2} + \frac{\partial^2 U}{\partial \eta^2} = 0$$

Such a mapping with $f(\zeta)$ analytic and $f'(\zeta) \neq 0$ is a conformal mapping.

If Laplace's equation is to be solved in the region exterior to a closed curve, then the point at infinity is in the domain D. For flow in a long channel (governed by the Laplace equation) the inlet and outlet are at infinity. In both cases the transformation

$$\zeta = \frac{a\,z + b}{z - z_0}$$

takes z_0 into infinity and hence maps D into a bounded domain D*.

4. Integral Transforms [34 – 39]

4.1. Fourier Transforms

Fourier Series [40]**.** Let $f(x)$ be a function that is periodic on $-\pi < x < \pi$. It can be expanded in a Fourier series

$$f(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos n\,x + b_n \sin n\,x)$$

where

$$a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x)\,\mathrm{d}x, \; a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \cos n\,x\,\mathrm{d}x,$$

$$b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \sin n\,x\,\mathrm{d}x$$

The values $\{a_n\}$ and $\{b_n\}$ are called the finite cosine and sine transform of f, respectively. Because

$$\cos n\,x = \frac{1}{2}\left(\mathrm{e}^{\mathrm{i}nx} + \mathrm{e}^{-\mathrm{i}nx}\right)$$

$$\text{and } \sin n\,x = \frac{1}{2\mathrm{i}}\left(\mathrm{e}^{\mathrm{i}nx} - \mathrm{e}^{-\mathrm{i}nx}\right)$$

the Fourier series can be written as

$$f(x) = \sum_{n=-\infty}^{\infty} c_n \mathrm{e}^{-\mathrm{i}nx}$$

where

$$c_n = \begin{cases} \frac{1}{2}(a_n + \mathrm{i}\,b_n) & \text{for} \quad n \geq 0 \\ \frac{1}{2}(a_{-n} - \mathrm{i}\,b_{-n}) & \text{for} \quad n < 0 \end{cases}$$

and

$$c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(x)\,\mathrm{e}^{\mathrm{i}nx}\,\mathrm{d}x$$

If f is real

$$c_{-n} = c_n^*.$$

If f is continuous and piecewise continuously differentiable

$$f'(x) = \sum_{-\infty}^{\infty} (-\mathrm{i}\,n)\,c_n \mathrm{e}^{-\mathrm{i}nx}$$

If f is twice continuously differentiable

$$f''(x) = \sum_{-\infty}^{\infty} \left(-n^2\right) c_n \mathrm{e}^{-\mathrm{i}nx}$$

Inversion. The Fourier series can be used to solve linear partial differential equations with constant coefficients. For example, in the problem

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2}$$

$$T(x, 0) = f(x)$$

$$T(-\pi, t) = T(\pi, t)$$

Let

$$T = \sum_{-\infty}^{\infty} c_n(t)\,\mathrm{e}^{-\mathrm{i}nx}$$

Then,

$$\sum_{-\infty}^{\infty} \frac{\mathrm{d}c_n}{\mathrm{d}t}\,\mathrm{e}^{-\mathrm{i}nx} = \sum_{-\infty}^{\infty} c_n(t)\left(-n^2\right)\mathrm{e}^{-\mathrm{i}nx}$$

Thus, $c_n(t)$ satisfies

$$\frac{\mathrm{d}c_n}{\mathrm{d}t} = -n^2\,c_n, \text{ or } c_n = c_n(0)\,\mathrm{e}^{-n^2 t}$$

Let $c_n(0)$ be the Fourier coefficients of the initial conditions:

$$f(x) = \sum_{-\infty}^{\infty} c_n(0)\,\mathrm{e}^{-\mathrm{i}nx}$$

The formal solution to the problem is

$$T = \sum_{-\infty}^{\infty} c_n(0)\,\mathrm{e}^{-n^2 t}\mathrm{e}^{-\mathrm{i}nx}$$

Fourier Transform [40]**.** When the function $f(x)$ is defined on the entire real line, the Fourier transform is defined as

$$\boldsymbol{F}[f] \equiv \hat{f}(\omega) = \int_{-\infty}^{\infty} f(x)\,\mathrm{e}^{\mathrm{i}\omega x}\mathrm{d}x$$

This integral converges if

$$\int_{-\infty}^{\infty} |f(x)|\,\mathrm{d}x$$

does. The inverse transformation is

$$f(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \hat{f}(\omega)\,\mathrm{e}^{-\mathrm{i}\omega x}\mathrm{d}\omega$$

If $f(x)$ is continuous and piecewise continuously differentiable,

$$\int_{-\infty}^{\infty} f(x)\,\mathrm{e}^{\mathrm{i}\omega x}\mathrm{d}x$$

converges for each ω, and

$$\lim_{x\to\pm\infty} f(x) = 0$$

then

$$\boldsymbol{F}\left[\frac{\mathrm{d}f}{\mathrm{d}x}\right] = -\mathrm{i}\omega\boldsymbol{F}[f]$$

If f is real $F[f(-\omega)] = F[f(\omega)^*]$. The real part is an even function of ω and the imaginary part is an odd function of ω.

A function $f(x)$ is *absolutely integrable* if the improper integral

$$\int_{-\infty}^{\infty} |f(x)|\,\mathrm{d}x$$

has a finite value. Then the improper integral

$$\int_{-\infty}^{\infty} f(x)\,\mathrm{d}x$$

converges. The function is *square integrable* if

$$\int_{-\infty}^{\infty} |f(x)|^2\mathrm{d}x$$

has a finite value. If $f(x)$ and $g(x)$ are square integrable, the product $f(x)\,g(x)$ is absolutely integrable and satisfies the Schwarz inequality:

$$\left|\int_{-\infty}^{\infty} f(x)\,g(x)\,\mathrm{d}x\right|^2 \le \int_{-\infty}^{\infty} |f(x)|^2\mathrm{d}x \int_{-\infty}^{\infty} |g(x)|^2\mathrm{d}x$$

The triangle inequality is also satisfied:

$$\left\{\int_{-\infty}^{\infty} |f+g|^2\mathrm{d}x\right\}^{1/2} \le \left\{\int_{-\infty}^{\infty} |f|^2\mathrm{d}x\right\}^{1/2}\left\{\int_{-\infty}^{\infty} |g|^2\mathrm{d}x\right\}^{1/2}$$

A sequence of square integrable functions $f_n(x)$ converges in the mean to a square integrable function $f(x)$ if

$$\lim_{n\to\infty}\int_{-\infty}^{\infty} |f(x) - f_n(x)|^2\mathrm{d}x = 0$$

The sequence also satisfies the Cauchy criterion

$$\lim_{\substack{n\to\infty\\ m\to\infty}}\int_{-\infty}^{\infty} |f_n - f_m|^2\mathrm{d}x = 0$$

Theorem [40, p. 307]. If a sequence of square integrable functions $f_n(x)$ converges to a function $f(x)$ uniformly on every finite interval $a \le x \le b$, and if it satisfies Cauchy's criterion, then $f(x)$ is square integrable and $f_n(x)$ converges to $f(x)$ in the mean.

Theorem (Riesz – Fischer) [40, p. 308]. To every sequence of square integrable functions $f_n(x)$ that satisfy Cauchy's criterion, there corresponds a square integrable function $f(x)$ such that $f_n(x)$ converges to $f(x)$ in the mean. Thus, the limit in the mean of a sequence of functions is defined to within a null function.

Square integrable functions satisfy the Parseval equation.

$$\int_{-\infty}^{\infty} \left|\hat{f}(\omega)\right|^2 \mathrm{d}\omega = 2\pi \int_{-\infty}^{\infty} |f(x)|^2 \mathrm{d}x$$

This is also the total power in a signal, which can be computed in either the time or the frequency domain. Also

$$\int_{-\infty}^{\infty} \hat{f}(\omega)\, \hat{g}*(\omega)\, \mathrm{d}\omega = 2\pi \int_{-\infty}^{\infty} f(x)\, g*(x)\, \mathrm{d}x$$

Fourier transforms can be used to solve differential equations too. Then it is necessary to find the inverse transformation. If $f(x)$ is square integrable, the Fourier transform of its Fourier transform is $2\pi f(-x)$, or

$$f(x) = \boldsymbol{F}\left[\hat{f}(\omega)\right] = \frac{1}{2\pi}\int_{-\infty}^{\infty} \hat{f}(\omega)\, \mathrm{e}^{-\mathrm{i}\omega x}\mathrm{d}\omega$$

$$= \frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x)\, \mathrm{e}^{\mathrm{i}\omega x}\mathrm{d}x e^{-\mathrm{i}\omega x}\mathrm{d}\omega$$

$$f(x) = \frac{1}{2\pi}\boldsymbol{F}\left[\boldsymbol{F} f(-x)\right] \text{ or } f(-x) = \frac{1}{2\pi}\boldsymbol{F}\left[\boldsymbol{F}[f]\right]$$

Properties of Fourier Transforms [40, p. 324], [15].

$$\boldsymbol{F}\left[\frac{\mathrm{d}f}{\mathrm{d}x}\right] = -\mathrm{i}\,\omega\,\boldsymbol{F}[f] = \mathrm{i}\,\omega\hat{f}$$

$$\boldsymbol{F}[\mathrm{i}\,x\,f(x)] = \frac{\mathrm{d}}{\mathrm{d}\omega}\boldsymbol{F}[f] = \frac{\mathrm{d}}{\mathrm{d}\omega}\hat{f}$$

$$\boldsymbol{F}[f(a\,x-b)] = \frac{1}{|a|}\mathrm{e}^{\mathrm{i}\omega b/a}\hat{f}\left(\frac{\omega}{a}\right)$$

$$\boldsymbol{F}\left[\mathrm{e}^{\mathrm{i}cx} f(x)\right] = \hat{f}(\omega+c)$$

$$\boldsymbol{F}[\cos\omega_0 x\, f(x)] = \frac{1}{2}\left[\hat{f}(\omega+\omega_0) + \hat{f}(\omega-\omega_0)\right]$$

$$\boldsymbol{F}[\sin\omega_0 x\, f(x)] = \frac{1}{2\mathrm{i}}\left[\hat{f}(\omega+\omega_0) - \hat{f}(\omega-\omega_0)\right]$$

$$\boldsymbol{F}\left[\mathrm{e}^{-\mathrm{i}\omega_0 x} f(x)\right] = \hat{f}(\omega-\omega_0)$$

If $f(x)$ is real, then $f(-\omega) = \hat{f}*(\omega)$. If $f(x)$ is imaginary, then $\hat{f}(-\omega) = -\hat{f}*(\omega)$. If $f(x)$ is even, then $\hat{f}(\omega)$ is even. If $f(x)$ is odd, then $\hat{f}(\omega)$ is odd. If $f(x)$ is real and even, then $\hat{f}(\omega)$ is real and even. If $f(x)$ is real and odd, then $\hat{f}(\omega)$ is imaginary and odd. If $f(x)$ is imaginary and even, then $\hat{f}(\omega)$ is imaginary and even. If $f(x)$ is imaginary and odd, then $\hat{f}(\omega)$ is real and odd.

Convolution [40, p. 326].

$$f*h(x_0) \equiv \int_{-\infty}^{\infty} f(x_0-x)\, h(x)\, \mathrm{d}x$$

$$= \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\omega x_0}\hat{f}(-\omega)\,\hat{h}(\omega)\,\mathrm{d}\omega$$

Theorem. The product

$$\hat{f}(\omega)\,\hat{h}(\omega)$$

is the Fourier transform of the convolution product $f*h$. The convolution permits finding inverse transformations when solving differential equations. To solve

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2}$$

$$T(x,0) = f(x), -\infty<x<\infty$$

T bounded

take the Fourier transform

$$\frac{\mathrm{d}\hat{T}}{\mathrm{d}t} + \omega^2\hat{T} = 0$$

$$\hat{T}(\omega,0) = \hat{f}(\omega)$$

The solution is

$$\hat{T}(\omega,t) = \hat{f}(\omega)\,\mathrm{e}^{-\omega^2 t}$$

The inverse transformation is

$$T(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega x}\,\hat{f}(\omega)\,\mathrm{e}^{-\omega^2 t}\mathrm{d}\omega$$

Because

$$\mathrm{e}^{-\omega^2 t} = \boldsymbol{F}\left[\frac{1}{\sqrt{4\pi t}}\,\mathrm{e}^{-x^2/4t}\right]$$

the convolution integral can be used to write the solution as

$$T(x,t) = \frac{1}{\sqrt{4\pi t}}\int_{-\infty}^{\infty} f(y)\,\mathrm{e}^{-(x-y)^2/4t}\mathrm{d}y$$

Finite Fourier Sine and Cosine Transform [41]. In analogy with finite Fourier transforms (on $-\pi$ to π) and Fourier transforms (on $-\infty$ to $+\infty$), finite Fourier sine and cosine transforms (0 to π) and Fourier sine and cosine transforms (on 0 to $+\infty$) can be defined.

The finite Fourier sine and cosine transforms are

$$f_s(n) = \boldsymbol{F}_s^n[f] = \frac{2}{\pi}\int_0^\pi f(x)\sin n x \mathrm{d}x,$$

$$n = 1, 2, \ldots,$$

$$f_c(n) = \boldsymbol{F}_c^n[f] = \frac{2}{\pi}\int_0^\pi f(x)\cos n x \mathrm{d}x$$

$$n = 0, 1, 2, \ldots$$

$$f(x) = \sum_{n=1}^{\infty} f_s(n)\sin n x,$$

$$f(x) = \frac{1}{2} f_c(0) + \sum_{n=1}^{\infty} f_c(n)\cos n x$$

They obey the operational properties

$$\boldsymbol{F}_s^n\left[\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\right] = -n^2 \boldsymbol{F}_s^n[f] + \frac{2n}{\pi}[f(0) - (-1)^n f(\pi)]$$

f, f' are continuous, f'' is piecewise continuous on $0 \le x \le \pi$.

$$\left.\begin{aligned} &f_s(n)\cos nk \\ &= \boldsymbol{F}_s^n[\tfrac{1}{2} f_1(x-k) + \tfrac{1}{2} f_1(x+k)] \\ &f_s(n)(-1)^{n+1} = \boldsymbol{F}_s^n[f(\pi - x)] \end{aligned}\right\} \begin{aligned} &f \text{ is piecewise} \\ &\text{continuous on} \\ &0 \le x \le \pi \end{aligned}$$

and f_1 is the extension of f, k is a constant

$$\left.\begin{aligned} &f_1(x) = f(x) \quad 0 < x < \pi \\ &f_1(-x) = -f_1(x) \\ &f_1(x + 2\pi) = f_1(x) \end{aligned}\right\} -\infty < x < \infty$$

Also,

$$\boldsymbol{F}_c^n\left[\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\right] = -n^2 \boldsymbol{F}_c^n[f] - \frac{2}{\pi}\frac{\mathrm{d}f}{\mathrm{d}x}(0) + (-1)^n \frac{2}{\pi}\frac{\mathrm{d}f}{\mathrm{d}x}(\pi)$$

$$f_c(n)\cos nk = \boldsymbol{F}_c^n\left[\tfrac{1}{2} f_2(x-k) + \tfrac{1}{2} f_2(x+k)\right]$$

$$f_c(n)(-1)^n = \boldsymbol{F}_c^n[f(\pi - x)]$$

and f_2 is the extension of f.

$$\left.\begin{aligned} &f_2(x) = f(x) \quad 0 < x < \pi \\ &f_2(-x) = f_2(x) \\ &f_2(x + 2\pi) = f_2(x) \end{aligned}\right\} -\infty < x < \infty$$

Table 3. Finite sine transforms [41]

$f_s(n) = \int_0^\pi F(x)\sin n x \mathrm{d}x \ (n = 1, 2, \ldots)$	$F(x) \ (0<x<\pi)$
$(-1)^{n+1} f_s(n)$	$F(\pi - x)$
$\frac{1}{n}$	$\frac{(\pi - x)}{\pi}$
$\frac{(-1)^{n+1}}{n}$	$\frac{x}{\pi}$
$\frac{1-(-1)^n}{n}$	1
$\frac{\pi}{n^2}\sin n c \ (0<c<\pi)$	$\begin{cases} (\pi - c)x & (x \le c) \\ c(\pi - x) & (x \ge c) \end{cases}$
$\frac{\pi}{n}\cos n c \ (0<c<\pi)$	$\begin{cases} -x & (x<c) \\ \pi - x & (x) \end{cases}$
$\frac{\pi^2(-1)^{n-1}}{n} - \frac{2[1-(-1)^n]}{n^3}$	x^2
$\pi(-1)^n\left(\frac{6}{n^3} - \frac{\pi^2}{n}\right)$	x^3
$\frac{n}{n^2+c^2}[1-(-1)^n e^{c\pi}]$	e^{cx}
$\frac{n}{n^2+c^2}$	$\frac{\sinh c(\pi - x)}{\sinh c\pi}$
$\frac{n}{n^2-k^2} \ (\lvert k\rvert \ne 0, 1, 2, \ldots)$	$\frac{\sin k(\pi - x)}{\sin k\pi}$
$0 \ (n \ne m); f_s(m) = \frac{\pi}{2}$	$\sin m x \ (m = 1, 2, \ldots)$
$\frac{n}{n^2-k^2}[1-(-1)^n \cos k x]$	$\cos k x \ (\lvert k\rvert \ne 1, 2, \ldots)$
$\frac{n}{n^2-m^2}[1-(-1)^{n+m}]$, $(n \ne m); f_s(m) = 0$	$\cos m x \ (m = 1, 2, \ldots)$

Also,

$$\boldsymbol{F}_s^n\left[\frac{\mathrm{d}f}{\mathrm{d}x}\right] = -n\boldsymbol{F}_c^n[f]$$

$$\boldsymbol{F}_c^n\left[\frac{\mathrm{d}f}{\mathrm{d}x}\right] = n\boldsymbol{F}_s^n[f] - \frac{2}{\pi} f(0) + (-1)^n \frac{2}{\pi} f(\pi)$$

When two functions $F(x)$ and $G(x)$ are defined on the interval $-2\pi < x < 2\pi$, the function

$$F(x) * G(x) = \int_{-\pi}^{\pi} f(x-y)\, g(y)\, \mathrm{d}y$$

is the convolution on $-\pi < x < \pi$. If F and G are both even or both odd, the convolution is even; it is odd if one function is even and the other odd. If F and G are piecewise continuous on $0 \le x \le \pi$, then

$$f_s(n)\, g_s(n) = \boldsymbol{F}_c^n\left[-\tfrac{1}{2} F_1(x) * G_1(x)\right]$$

$$f_s(n)\, g_c(n) = \boldsymbol{F}_s^n\left[\tfrac{1}{2} F_1(x) * G_2(x)\right]$$

$$f_c(n)\, g_c(n) = \boldsymbol{F}_c^n\left[\tfrac{1}{2} F_2(x) * G_2(x)\right]$$

where F_1 and G_1 are odd extensions of F and G, respectively, and F_2 and G_2 are even extensions of F and G, respectively. Finite sine and cosine transforms are listed in Tables 3 and 4.

Table 4. Finite cosine transforms [41]

$f_c(n) = \int_0^\pi F(x)\cos nx\,\mathrm{d}x \; (n = 0,1,\ldots)$	$F(x) \;\; (0<x<\pi)$

$\frac{1}{n^2-k^2}$ $(\lvert k\rvert \neq 0,1,\ldots)$	$-\frac{\cos k(\pi-x)}{k\sin kx}$
0 $(n\neq m)$; $f_c(m) = \frac{\pi}{2}$ $(m = 1,2,\ldots)$	$\cos mx$

The material is reproduced with permission of McGrawHill, Inc.

On the semi-infinite domain, $0 < x < \infty$, the Fourier sine and cosine transforms are

$$\boldsymbol{F}_{\mathrm{s}}^{\omega}[f] \equiv \int_0^\infty f(x)\sin\omega x\,\mathrm{d}x,$$

$$\boldsymbol{F}_{\mathrm{c}}^{\omega}[f] \equiv \int_0^\infty f(x)\cos\omega x\,\mathrm{d}x \text{ and}$$

$$f(x) = \frac{2}{\pi}\boldsymbol{F}_{\mathrm{s}}^{\omega\prime}\left[\boldsymbol{F}_{\mathrm{s}}^{\omega}[f]\right],\; f(x) = \frac{2}{\pi}\boldsymbol{F}_{\mathrm{c}}^{\omega\prime}\left[\boldsymbol{F}_{\mathrm{c}}^{\omega}[f]\right]$$

The sine transform is an odd function of ω, whereas the cosine function is an even function of ω. Also,

$$\boldsymbol{F}_{\mathrm{s}}^{\omega}\left[\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\right] = f(0)\,\omega - \omega^2\boldsymbol{F}_{\mathrm{s}}^{\omega}[f]$$

$$\boldsymbol{F}_{\mathrm{c}}^{\omega}\left[\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}\right] = -\frac{\mathrm{d}f}{\mathrm{d}x}(0) - \omega^2\boldsymbol{F}_{\mathrm{c}}^{\omega}[f]$$

provided $f(x)$ and $f'(x) \to 0$ as $x \to \infty$. Thus, the sine transform is useful when $f(0)$ is known and the cosine transform is useful when $f'(0)$ is known.

Hsu and Dranoff [42] solved a chemical engineering problem by applying finite Fourier transforms and then using the fast Fourier transform (see Chap. 2).

4.2. Laplace Transforms

Consider a function $F(t)$ defined for $t > 0$. The Laplace transform of $F(t)$ is [41]

$$\boldsymbol{L}[F] = f(s) = \int_0^\infty e^{-st}F(t)\,\mathrm{d}t$$

The Laplace transformation is linear, that is,

$$\boldsymbol{L}[F+G] = \boldsymbol{L}[F] + \boldsymbol{L}[G]$$

Thus, the techniques described herein can be applied only to linear problems. Generally, the assumptions made below are that $F(t)$ is at least piecewise continuous, that it is continuous in each finite interval within $0 < t < \infty$, and that it may take a jump between intervals. It is also of exponential order, meaning $e^{-\alpha t}\lvert F(t)\rvert$ is bounded for all $t > T$, for some finite T.

The unit step function is

$$S_k(t) = \begin{cases} 0 & 0\le t<k \\ 1 & t>k \end{cases}$$

and its Laplace transform is

$$\boldsymbol{L}[S_k(t)] = \frac{e^{-ks}}{s}$$

In particular, if $k = 0$ then

$$\boldsymbol{L}[1] = \frac{1}{s}$$

The Laplace transforms of the first and second derivatives of $F(t)$ are

$$\boldsymbol{L}\left[\frac{\mathrm{d}F}{\mathrm{d}t}\right] = s\,f(s) - F(0)$$

$$\boldsymbol{L}\left[\frac{\mathrm{d}^2F}{\mathrm{d}t^2}\right] = s^2 f(s) - s\,F(0) - \frac{\mathrm{d}F}{\mathrm{d}t}(0)$$

More generally,

$$\boldsymbol{L}\left[\frac{\mathrm{d}^nF}{\mathrm{d}t^n}\right] = s^n f(s) - s^{n-1}F(0) - s^{n-2}\frac{\mathrm{d}F}{\mathrm{d}t}(0) - \cdots - \frac{\mathrm{d}^{n-1}F}{\mathrm{d}t^{n-1}}(0)$$

The inverse Laplace transformation is

$$F(t) = \boldsymbol{L}^{-1}[f(s)] \text{ where } f(s) = \boldsymbol{L}[F]$$

The inverse Laplace transformation is not unique because functions that are identical except for

isolated points have the same Laplace transform. They are unique to within a null function. Thus, if

$$\boldsymbol{L}[F_1] = f(s) \text{ and } \boldsymbol{L}[F_2] = f(s)$$

it must be that

$$F_2 = F_1 + N(t)$$

$$\text{where} \int_0^T (N(t))\,\mathrm{d}t = 0 \text{ for every } T$$

Laplace transforms can be inverted by using Table 5, but knowledge of several rules is helpful.

Table 5. Laplace transforms (see [23] for a more complete list)

$L[F]$	$F(t)$
$\frac{1}{s}$	1
$\frac{1}{s^2}$	t
$\frac{1}{s^n}$	$\frac{t^{n-1}}{(n-1)!}$
$\frac{1}{\sqrt{s}}$	$\frac{1}{\sqrt{\pi t}}$
$s^{-3/2}$	$2\sqrt{t/\pi}$
$\frac{\Gamma(k)}{s^k}$ $(k>0)$	t^{k-1}
$\frac{1}{s-a}$	e^{at}
$\frac{1}{(s-a)^n}$ $(n = 1,2,\ldots)$	$\frac{1}{(n-1)!}t^{n-1}e^{at}$
$\frac{\Gamma(k)}{(s-a)^k}$ $(k>0)$	$t^{k-1}\,e^{at}$
$\frac{1}{(s-a)(s-b)}$	$\frac{1}{a-b}\left(e^{at}-e^{bt}\right)$
$\frac{s}{(s-a)(s-b)}$	$\frac{1}{a-b}\left(ae^{at}-be^{bt}\right)$
$\frac{1}{s^2+a^2}$	$\frac{1}{a}\sin a\,t$
$\frac{s}{s^2+a^2}$	$\cos a\,t$
$\frac{1}{s^2-a^2}$	$\frac{1}{a}\sinh a\,t$
$\frac{s}{s^2-a^2}$	$\cosh a\,t$
$\frac{s}{(s^2+a^2)^2}$	$\frac{t}{2a}\sin a\,t$
$\frac{s^2-a^2}{(s^2+a^2)^2}$	$t\cos a\,t$
$\frac{1}{(s-a)^2+b^2}$	$\frac{1}{b}e^{a\,t}\sin b\,t$
$\frac{s-a}{(s-a)^2+b^2}$	$e^{at}\cos b\,t$

Substitution.

$$f(s-a) = \boldsymbol{L}\left[e^{at}\,F(t)\right]$$

This can be used with polynomials. Suppose

$$f(s) = \frac{1}{s} + \frac{1}{s+3} = \frac{2s+3}{s(s+3)}$$

Because

$$\boldsymbol{L}[1] = \frac{1}{s}$$

Then

$$F(t) = 1 + e^{-3t},\ t \geq 0$$

More generally, translation gives the following.

Translation.

$$f(a\,s-b) = f\left[a\left(s-\frac{b}{a}\right)\right] = \boldsymbol{L}\left[\frac{1}{a}\,e^{bt/a}\,F\left(\frac{t}{a}\right)\right],$$

$$a>0$$

The step function

$$S(t) = \begin{cases} 0 & 0 \leq t < \frac{1}{h} \\ 1 & \frac{1}{h} \leq t < \frac{2}{h} \\ 2 & \frac{2}{h} \leq t < \frac{3}{h} \end{cases}$$

has the Laplace transform

$$\boldsymbol{L}[S(t)] = \frac{1}{s}\frac{1}{1-e^{-hs}}$$

The Dirac delta function $\delta(t-t_0)$ (see Equation 116 in → Mathematical Modeling) has the property

$$\int_0^\infty \delta(t-t_0)\,F(t)\,\mathrm{d}t = F(t_0)$$

Its Laplace transform is

$$\boldsymbol{L}[\delta(t-t_0)] = e^{-st_0},\ t_0 \geq 0,\ s>0$$

The square wave function illustrated in Figure 10 has Laplace transform

$$\boldsymbol{L}[F_c(t)] = \frac{1}{s}\tanh\frac{c\,s}{2}$$

The triangular wave function illustrated in Figure 11 has Laplace transform

$$L[T_c(t)] = \frac{1}{s^2}\tanh\frac{c\,s}{2}$$

Other Laplace transforms are listed in Table 5.

Figure 10. Square wave function

Figure 11. Triangular wave function

Convolution properties are also satisfied:

$$F\ (t)\ *G\ (t) = \int_0^t F\ (\tau)\ G\ (t-\tau)\,\mathrm{d}\tau$$

and

$$f\,(s)\,g\,(s) = \boldsymbol{L}\,[F\,(t)\ *G\,(t)]$$

Derivatives of Laplace Transforms. The Laplace integrals $\boldsymbol{L}\,[F\,(t)]$, $\boldsymbol{L}\,[t\,F\,(t)]$, $\boldsymbol{L}\,[t^2\,F\,(t)]$, . . . are uniformly convergent for $s_1 \geq \alpha$ and

$$\lim_{s\to\infty} f\ (s) = 0,\ \lim_{s\to\infty} \boldsymbol{L}\,[t^n\ F\ (t)] = 0, n = 1, 2,\ldots$$

and

$$\frac{\mathrm{d}^n f}{\mathrm{d}s^n} = \boldsymbol{L}\,[(-t)^n\ F\ (t)]$$

Integration of Laplace Transforms.

$$\int_s^\infty f\ (\xi)\,\mathrm{d}\xi = \boldsymbol{L}\left[\frac{F\ (t)}{t}\right]$$

If $F\ (t)$ is a periodic function, $F\ (t) = F\ (t + a)$, then

$$f\ (s) = \tfrac{1}{1-\mathrm{e}^{-as}}\int_0^a \mathrm{e}^{-st} F\ (t)\,\mathrm{d}t,$$

where $F\ (t) = F\ (t+a)$

Partial Fractions [43]**.** Suppose $q\ (s)$ has m factors

$$q\ (s) = (s-a_1)\,(s-a_2)\cdots(s-a_m)$$

All the factors are linear, none are repeated, and the a_n are all distinct. If $p\ (s)$ has a smaller degree than $q\ (s)$, the Heaviside expansion can be used to evaluate the inverse transformation:

$$\boldsymbol{L}^{-1}\left[\frac{p\ (s)}{q\ (s)}\right] = \sum_{i=1}^{m} \frac{p\ (a_i)}{q'\ (a_i)}\,\mathrm{e}^{a_i t}$$

If the factor $(s - a)$ is repeated m times, then

$$f\ (s) = \tfrac{p\,(s)}{q\,(s)} = \tfrac{A_m}{(s-a)^m} + \tfrac{A_{m-1}}{(s-a)^{m-1}} + \cdots + \tfrac{A_1}{s-a} + h\ (s)$$

where

$$\varphi\ (s) \equiv \tfrac{(s-a)^m\ p\,(s)}{q\,(s)}$$

$$A_m = \varphi\ (a)\,,\ A_k = \tfrac{1}{(m-k)!}\,\tfrac{\mathrm{d}^{m-k}\ \varphi\,(s)}{\mathrm{d}s^{m-k}}|_a,$$

$$k = 1,\ldots,m-1$$

The term $h\ (s)$ denotes the sum of partial fractions not under consideration. The inverse transformation is then

$$F\ (t) = \mathrm{e}^{at}\left(A_m\frac{t^{m-1}}{(m-1)\,!} + A_{m-1}\frac{t^{m-2}}{(m-2)\,!} + \cdots + A_2\frac{t}{1!} + A_1\right) + H\ (t)$$

The term in $F\ (t)$ corresponding to

$s-a$ in $q\ (s)$ is $\varphi\ (a)\ \mathrm{e}^{a\,t}$

$(s-a)^2$ in $q\ (s)$ is $[\varphi'\ (a) + \varphi\ (a)\ t]\,\mathrm{e}^{a\,t}$

$(s-a)^3$ in $q\ (s)$ is $\frac{1}{2}\left[\varphi''\,(a) + 2\varphi'\ (a)\ t + \varphi\ (a)\ t^2\right]\mathrm{e}^{a\,t}$

For example, let

$$f\ (s) = \frac{1}{(s-2)\ (s-1)^2}$$

For the factor $s - 2$,

$$\varphi\ (s) = \frac{1}{(s-1)^2},\ \varphi\ (2) = 1$$

For the factor $(s - 1)^2$,

$$\varphi\ (s) = \tfrac{1}{s-2}, \varphi'\ (s) = -\tfrac{1}{(s-2)^2}$$

$$\varphi\ (1) = -1,\ \varphi'\,(1) = -1$$

The inverse Laplace transform is then

$$F\,(t) = \mathrm{e}^{2t} + [-1-t]\ \mathrm{e}^{t}$$

Quadratic Factors. Let $p(s)$ and $q(s)$ have real coefficients, and $q(s)$ have the factor

$$(s-a)^2+b^2, b>0$$

where a and b are real numbers. Then define $\varphi(s)$ and $h(s)$ and real constants A and B such that

$$f(s)=\frac{p(s)}{q(s)}=\frac{\varphi(s)}{(s-a)^2+b^2}$$
$$=\frac{A\,s+B}{(s-a)^2+b^2}+h(s)$$

Let φ_1 and φ_2 be the real and imaginary parts of the complex number $\varphi(a+\mathrm{i}\,b)$.

$$\varphi(a+\mathrm{i}\,b)\equiv\varphi_1+\mathrm{i}\,\varphi_2$$

Then

$$f(s)=\frac{1}{b}\frac{(s-a)\varphi_2+b\varphi_1}{(s-a)^2+b^2}+h(s)$$

$$F(t)=\frac{1}{b}\,\mathrm{e}^{at}\,(\varphi_2\cos b\,t+\varphi_1\sin b\,t)+H(t)$$

To solve ordinary differential equations by using these results:

$$Y''(t)-2Y'(t)+Y(t)=\mathrm{e}^{2t}$$

$$Y(0)=0, Y'(0)=0$$

Taking Laplace transforms

$$\boldsymbol{L}\left[Y''(t)\right]-2\boldsymbol{L}\left[Y'(t)\right]+\boldsymbol{L}\left[Y(t)\right]=\frac{1}{s-2}$$

using the rules

$$s^2\,y(s)-s\,Y(0)-Y'(0)-2\left[s\,y(s)-Y(0)\right]+y(s)=\frac{1}{s-2}$$

and combining terms

$$\left(s^2-2\,s+1\right)y(s)=\frac{1}{s-2}$$

$$y(s)=\frac{1}{(s-2)(s-1)^2}$$

lead to

$$Y(t)=\mathrm{e}^{2t}-(1+t)\,\mathrm{e}^{t}$$

To solve an integral equation:

$$Y(t)=a+2\int_0^t Y(\tau)\cos(t-\tau)\,\mathrm{d}\tau$$

it is written as

$$Y(t)=a+Y(t)*\cos t$$

Then the Laplace transform is used to obtain

$$y(s)=\frac{a}{s}+2\,y(s)\frac{s}{s^2+1}$$

$$\text{or } y(s)=\frac{a\left(s^2+1\right)}{s(s-1)^2}$$

Taking the inverse transformation gives

$$Y(t)=s\left[1+2t\mathrm{e}^{t}\right]$$

Next, let the variable s in the Laplace transform be complex. $F(t)$ is still a real-valued function of the positive real variable t. The properties given above are still valid for s complex, but additional techniques are available for evaluating the integrals. The real-valued function is O [exp (x_0t)]:

$$|F(t)|<M\mathrm{e}^{x_0t},\ z_0=x_0+\mathrm{i}\,y_0$$

The Laplace transform

$$f(s)=\int_0^\infty \mathrm{e}^{-st}\,F(t)\,\mathrm{d}t$$

is an analytic function of s in the half-plane $x>x_0$ and is absolutely convergent there; it is uniformly convergent on $x\geq x_1>x_0$.

$$\frac{\mathrm{d}^n f}{\mathrm{d}s^n}=\boldsymbol{L}\left[(-t)^n\,F(t)\right]\quad n=1,2,\ldots,x>x_0$$

$$\text{and } f^*(s)=f(s^*)$$

The functions $|f(s)|$ and $|x\,f(s)|$ are bounded in the half-plane $x\geq x_1>x_0$ and $f(s)\to 0$ as $|y|\to\infty$ for each fixed x. Thus,

$$|f(x+\mathrm{i}\,y)|<M,\ |x\,f(x+\mathrm{i}\,y)|<M,$$

$$x\geq x_1>x_0$$

$$\lim_{y\to\pm\infty} f(x+\mathrm{i}\,y)=0,\ x>x_0$$

If $F(t)$ is continuous, $F'(t)$ is piecewise continuous, and both functions are O [exp (x_0t)], then $|f(s)|$ is $O(1/s)$ in each half-plane $x\geq x_1>x_0$.

$$|s\,f(s)|<M$$

If $F(t)$ and $F'(t)$ are continuous, $F''(t)$ is piecewise continuous, and all three functions are O [exp (x_0t)], then

$$\left|s^2f(s)-s\,F(0)\right|<M, x\geq x_1>x_0$$

The additional constraint $F(0)=0$ is necessary and sufficient for $|f(s)|$ to be $O(1/s^2)$.

Inversion Integral [41]. Cauchy's integral formula for $f(s)$ analytic and $O(s^{-k})$ in a half-plane $x\geq y$, $k>0$, is

$$f(s)=\frac{1}{2\,\pi\mathrm{i}}\lim_{\beta\to\infty}\int_{\gamma-\mathrm{i}\beta}^{\gamma+\mathrm{i}\beta}\frac{f(z)}{s-z}\mathrm{d}z,\ \mathrm{Re}(s)>\gamma$$

Applying the inverse Laplace transformation on either side of this equation gives

$$F\ (t) = \frac{1}{2\,\pi \mathrm{i}} \lim_{\beta\to\infty} \int_{\gamma-\mathrm{i}\beta}^{\gamma+\mathrm{i}\beta} \mathrm{e}^{zt}\, f\ (z)\, \mathrm{d}z$$

If $F\ (t)$ is of order $O\ [\exp\ (x_0 t)]$ and $F\ (t)$ and $F'\ (t)$ are piecewise continuous, the inversion integral exists. At any point t_0, where $F\ (t)$ is discontinuous, the inversion integral represents the mean value

$$F\ (t_0) = \lim_{\varepsilon\to\infty} \frac{1}{2}\, [F\ (t_0+\varepsilon) + F\,(t_0-\varepsilon)]$$

When $t = 0$ the inversion integral represents 0.5 $F\ (O+)$ and when $t < 0$, it has the value zero.

If $f\ (s)$ is a function of the complex variable s that is analytic and of order $O\ (s^{-k-m})$ on $R\ (s) \geq x_0$, where $k > 1$ and m is a positive integer, then the inversion integral converges to $F\ (t)$ and

$$\frac{\mathrm{d}^n F}{\mathrm{d}t^n} = \frac{1}{2\,\pi \mathrm{i}} \lim_{\beta\to\infty} \int_{\gamma-\mathrm{i}\beta}^{\gamma+\mathrm{i}\beta} \mathrm{e}^{zt} z^n\, f\ (z)\, \mathrm{d}z,$$

$$n = 1,2,\ldots, m$$

Also $F\ (t)$ and its n derivatives are continuous functions of t of order $O\ [\exp\ (x_0 t)]$ and they vanish at $t = 0$.

$$F\,(0) = F'\,(0) = \cdots F^{(m)}\ (0) = 0$$

Series of Residues [41]. Let $f\ (s)$ be an analytic function except for a set of isolated singular points. An isolated singular point is one for which $f\ (z)$ is analytic for $0 < |z - z_0| < \varrho$ but z_0 is a singularity of $f\ (z)$. An isolated singular point is either a pole, a removable singularity, or an essential singularity. If $f\ (z)$ is not defined in the neighborhood of z_0 but can be made analytic at z_0 simply by defining it at some additional points, then z_0 is a *removable singularity*. The function $f\ (z)$ has a *pole* of order $k \geq 1$ at z_0 if $(z - z_0)^k\, f\ (z)$ has a removable singularity at z_0 whereas $(z - z_0)^{k-1}\, f\ (z)$ has an unremovable isolated singularity at z_0. Any isolated singularity that is not a pole or a removable singularity is an *essential* singularity.

Let the function $f\ (z)$ be analytic except for the isolated singular point $s_1, s_2, \ldots, s_n$. Let $\varrho_n\ (t)$ be the residue of $\mathrm{e}^{zt}\, f\ (z)$ at $z = s_n$ (for definition of residue, see Section 3.4). Then

$$F\ (t) = \sum_{n=1}^{\infty} \varrho_n\ (t)$$

When s_n is a simple pole

$$\varrho_n\ (t) = \lim_{z\to s_n} (z-s_n)\, \mathrm{e}^{zt}\, f\ (z)$$

$$= \mathrm{e}^{s_n t} \lim_{z\to s_n} (z-s_n)\ f\ (z)$$

When

$$f\ (z) = \frac{p\ (z)}{q\ (z)}$$

where $p\ (z)$ and $q\ (z)$ are analytic at $z = s_n$, $p\ (s_n) \neq 0$, then

$$\varrho_n\ (t) = \frac{p\ (s_n)}{q'\ (s_n)}\, \mathrm{e}^{s_n t}$$

If s_n is a removable pole of $f\ (s)$, of order m, then

$$\varphi_n\ (z) = (z-s_n)^m\, f\,(z)$$

is analytic at s_n and the residue is

$$\varrho_n\ (t) = \frac{\Phi_n\ (s_n)}{(m-1)!} \text{ where } \Phi_n\ (z) = \frac{\partial^{m-1}}{\partial z^{m-1}}\, \left[\varphi_n\ (z)\, \mathrm{e}^{zt}\right]$$

An important inversion integral is when

$$f\ (s) = \frac{1}{s} \exp\left(-s^{1/2}\right)$$

The inverse transform is

$$F\ (t) = 1 - \operatorname{erf}\left(\frac{1}{2\sqrt{t}}\right) = \operatorname{erfc}\left(\frac{1}{2\sqrt{t}}\right)$$

where erf is the error function and erfc the complementary error function.

4.3. Solution of Partial Differential Equations by Using Transforms

A common problem facing chemical engineers is to solve the heat conduction equation or diffusion equation

$$\varrho\, C_p \frac{\partial T}{\partial t} = k\, \frac{\partial^2 T}{\partial x^2} \text{ or } \frac{\partial c}{\partial t} = D\, \frac{\partial^2 c}{\partial x^2}$$

The equations can be solved on an infinite domain $-\infty < x < \infty$, a semi-infinite domain $0 \leq x < \infty$, or a finite domain $0 \leq x \leq L$. At a boundary, the conditions can be a fixed temperature $T\ (0, t) = T_0$ (boundary condition of the first kind, or Dirichlet condition), or a fixed flux $-k \frac{\partial T}{\partial x}\ (0,t) = q_0$ (boundary condition of the second kind, or Neumann condition), or a

combination $-k\frac{\partial T}{\partial x}(0,t) = h[T(0,t)-T_0]$ (boundary condition of the third kind, or Robin condition).

The functions T_0 and q_0 can be functions of time. All properties are constant (ϱ, C_p, k, D, h), so that the problem remains linear. Solutions are presented on all domains with various boundary conditions for the heat conduction problem.

$$\frac{\partial T}{\partial t} = \alpha\frac{\partial^2 T}{\partial x^2},\ \alpha = \frac{k}{\varrho C_p}$$

Problem 1. Infinite domain, on $-\infty < x < \infty$.

$T(x,0) = f(x)$, initial conditions

$T(x,t)$ bounded

Solution is via Fourier transforms

$$\hat{T}(\omega,t) = \int_{-\infty}^{\infty} T(x,t)\,\mathrm{e}^{\mathrm{i}\omega x}\,\mathrm{d}x$$

Applied to the differential equation

$$\boldsymbol{F}\left[\frac{\partial^2 T}{\partial x^2}\right] = -\omega^2\,\alpha\boldsymbol{F}[T]$$

$$\frac{\partial\hat{T}}{\partial t}+\omega^2\,\alpha\hat{T} = 0, \hat{T}(\omega,0) = \hat{f}(\omega)$$

By solving

$$\hat{T}(\omega,t) = \hat{f}(\omega)\,\mathrm{e}^{-\omega^2\alpha t}$$

the inverse transformation gives [40, p. 328], [44, p. 58]

$$T(x,t) = \frac{1}{2\pi}\lim_{L\to\infty}\int_{-L}^{L}\mathrm{e}^{-\mathrm{i}\omega x}\,\hat{f}(\omega)\,\mathrm{e}^{-\omega^2\alpha t}\mathrm{d}\omega$$

Another solution is via Laplace transforms; take the Laplace transform of the original differential equation.

$$s\,t(s,x)-f(x) = \alpha\frac{\partial^2 t}{\partial x^2}$$

This equation can be solved with Fourier transforms [40, p. 355]

$$t(s,x) = \frac{1}{2\sqrt{s\alpha}}\int_{-\infty}^{\infty}\mathrm{e}\left\{-\sqrt{\frac{s}{\alpha}}\,|x-y|\right\}f(y)\,\mathrm{d}y$$

The inverse transformation is [40, p. 357], [44, p. 53]

$$T(x,t) = \frac{1}{2\sqrt{\pi\,\alpha\,t}}\int_{-\infty}^{\infty}\mathrm{e}^{-(x-y)^2/4\alpha t}\,f(y)\,\mathrm{d}y$$

Problem 2. Semi-infinite domain, boundary condition of the first kind, on $0 \le x \le \infty$

$T(x,0) = T_0 =$ constant

$T(0,t) = T_1 =$ constant

The solution is

$$T(x,t) = T_0+[T_1-T_0]\left[1-\mathrm{erf}\left(x/\sqrt{4\alpha\,t}\right)\right]$$

$$\text{or } T(x,t) = T_0+(T_1-T_0)\ \mathrm{erfc}\left(x/\sqrt{4\alpha\,t}\right)$$

Problem 3. Semi-infinite domain, boundary condition of the first kind, on $0 \le x < \infty$

$T(x,0) = f(x)$

$T(0,t) = g(t)$

The solution is written as

$$T(x,t) = T_1(x,t)+T_2(x,t)$$

where

$$T_1(x,0) = f(x),\ T_2(x,0) = 0$$

$$T_1(0,t) = 0,\ T_2(0,t) = g(t)$$

Then T_1 is solved by taking the sine transform

$$U_1 = F_s^{\omega}[T_1]$$

$$\frac{\partial U_1}{\partial t} = -\omega^2\,\alpha\,U_1$$

$$U_1(\omega,0) = F_s^{\omega}[f]$$

Thus,

$$U_1(\omega,t) = F_s^{\omega}[f]\,\mathrm{e}^{-\omega^2\alpha t}$$

and [40, p. 322]

$$T_1(x,t) = \frac{2}{\pi}\int_0^{\infty}F_s^{\omega}[f]\,\mathrm{e}^{-\omega^2\alpha t}\sin\omega x\,\mathrm{d}\omega$$

Solve for T_2 by taking the sine transform

$$U_2 = F_s^{\omega}[T_2]$$

$$\frac{\partial U_2}{\partial t} = -\omega^2\,\alpha\,U_2+\alpha\,g(t)\,\omega$$

$$U_2(\omega,0) = 0$$

Thus,

$$U_2(\omega,t)=\int_0^t \mathrm{e}^{-\omega^2\alpha(t-\tau)}\alpha\omega\, g\,(\tau)\,\mathrm{d}\tau$$

and [40, p. 435]

$$T_2(x,t)=\frac{2\,\alpha}{\pi}\int_0^\infty \omega\sin\omega x\int_0^t \mathrm{e}^{-\omega^2\,\alpha(t-\tau)}\,g\,(\tau)\,\mathrm{d}\tau\mathrm{d}\omega$$

The solution for T_1 can also be obtained by Laplace transforms.

$$t_1=\boldsymbol{L}\,[T_1]$$

Applying this to the differential equation

$$st_1-f\,(x)=\alpha\,\frac{\partial^2 t_1}{\partial x^2},\ t_1\,(0,s)=0$$

and solving gives

$$t_1=\frac{1}{\sqrt{s\,\alpha}}\int_0^x \mathrm{e}^{-\sqrt{s/\alpha}(x'-x)}\,f\,(x')\,\mathrm{d}x'$$

and the inverse transformation is [40, p. 437], [44, p. 59]

$$T_1\,(x,t)= \tag{7}$$
$$\frac{1}{\sqrt{4\,\pi\,\alpha\,t}}\int_0^\infty\left[\mathrm{e}^{-(x-\xi)^2/4\alpha t}-\mathrm{e}^{-(x+\xi)^2/4\alpha t}\right]f\,(\xi)\,\mathrm{d}\xi$$

Problem 4. Semi-infinite domain, boundary conditions of the second kind, on $0\le x<\infty$.

$$T\,(x,0)=0$$

$$-k\frac{\partial T}{\partial x}\,(0,t)=q_0=\text{constant}$$

Take the Laplace transform

$$t\,(x,s)=L\,[T\,(x,t)]$$

$$s\,t=\alpha\,\tfrac{\partial^2 t}{\partial x^2}$$

$$-k\,\tfrac{\partial t}{\partial x}=\tfrac{q_0}{s}$$

The solution is

$$t\,(x,s)=\frac{q_0\sqrt{\alpha}}{k\,s^{3/2}}\mathrm{e}^{-x\sqrt{s/\alpha}}$$

The inverse transformation is [41, p. 131], [44, p. 75]

$$T\,(x,t)=\frac{q_0}{k}\left[2\sqrt{\frac{\alpha\,t}{\pi}}\,\mathrm{e}^{-x^2/4\alpha t}-x\,\mathrm{erfc}\left(\frac{x}{\sqrt{4\,\alpha\,t}}\right)\right]$$

Problem 5. Semi-infinite domain, boundary conditions of the third kind, on $0\le x<\infty$

$$T\,(x,0)=f\,(x)$$

$$k\frac{\partial T}{\partial x}\,(0,t)=h\;T\;(0,t)$$

Take the Laplace transform

$$s\,t-f\;(x)=\alpha\,\tfrac{\partial^2 t}{\partial x^2}$$

$$k\,\tfrac{\partial t}{\partial x}\,(0,s)=h\,t\;(0,s)$$

The solution is

$$t\;(x,s)=\int_0^\infty f\;(\xi)\;g\;(x,\xi,s)\,\mathrm{d}\xi$$

where [41, p. 227]

$$2\sqrt{s/\alpha}\,g\;(x,\xi,s)=\exp\left(-\,|x-\xi|\,\sqrt{s/\alpha}\right)$$
$$+\tfrac{\sqrt{s}-h\sqrt{\alpha}/k}{\sqrt{s}+h\sqrt{\alpha}/k}\exp\left[-\,(x+\xi)\;\sqrt{s/\alpha}\right]$$

One form of the inverse transformation is [41, p. 228]

$$T\;(x,t)=\tfrac{2}{\pi}\int_0^\infty \mathrm{e}^{-\beta^2\alpha t}\cos\;[\beta\,x-\mu\;(\beta)]\int_0^\infty f\,(\xi)$$
$$\cos\;[\beta\,\xi-\mu\;(\beta)]\;\mathrm{d}\xi\mathrm{d}\beta$$

$$\mu\;(\beta)=\arg\;(\beta+i\,h/k)$$

Another form of the inverse transformation when $f=T_0=$ constant is [41, p. 231], [44, p. 71]

$$T\;(x,t)=T_0\left[\mathrm{erf}\left(\frac{x}{\sqrt{4\,\alpha\,t}}\right)+\mathrm{e}^{hx/k}\,\mathrm{e}^{h^2\,\alpha t/k^2}\right.$$
$$\left.\mathrm{erfc}\left(\frac{h\sqrt{\alpha t}}{k}+\frac{x}{\sqrt{4\,\alpha\,t}}\right)\right]$$

Problem 6. Finite domain, boundary condition of the first kind

$$T\,(x,0)=T_0=\text{constant}$$

$$T\,(0,t)=T\;(L,t)=0$$

Take the Laplace transform

$$s\,t\,(x,s)-T_0=\alpha\,\frac{\partial^2 t}{\partial x^2}$$

$$t\,(0,s)=t\,(L,s)=0$$

The solution is

$$t\;(x,s)=-\frac{T_0}{s}\frac{\sinh\sqrt{\frac{s}{\alpha}}\,x}{\sinh\sqrt{\frac{s}{\alpha}}\,L}-\frac{T_0}{s}\frac{\sinh\sqrt{\frac{s}{\alpha}}\,(L-x)}{\sinh\sqrt{\frac{s}{\alpha}}\,L}+\frac{T_0}{s}$$

The inverse transformation is [41, p. 220], [44, p. 96]

$$T\ (x,t) = \frac{2}{\pi}\, T_0 \sum\nolimits_{n=1,3,5,\ldots} \frac{2}{n}\, \mathrm{e}^{-n^2\pi^2\alpha t/L^2} \sin\frac{n\,\pi\,x}{L}$$

or (depending on the inversion technique) [40, pp. 362, 438]

$$T\ (x,t) = \frac{T_0}{\sqrt{4\,\pi\,\alpha\,t}} \int_0^L \sum_{n=-\infty}^{\infty} \left[\mathrm{e}^{-[(x-\xi)+2nL]^2/4\alpha t} - \mathrm{e}^{-[(x+\xi)+2nL]^2/4\alpha t}\right] \mathrm{d}\xi$$

Problem 7. Finite domain, boundary condition of the first kind

$$T\,(x,0) = 0$$

$$T\,(0,t) = 0$$

$$T\,(L,0) = T_0 = \text{constant}$$

Take the Laplace transform

$$s\,t\ (x,s) = \alpha\ \tfrac{\partial^2 t}{\partial x^2}$$

$$t\ (0,s) = 0, t\ (L,s) = \tfrac{T_0}{s}$$

The solution is

$$t\ (x,s) = \frac{T_0}{s}\,\frac{\sinh\frac{x}{L}\sqrt{s/\alpha}}{\sinh\sqrt{s/\alpha}}$$

and the inverse transformation is [41, p. 201], [44, p. 313]

$$T\ (x,t) = T_0\left[\frac{x}{L} + \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\,\mathrm{e}^{-n^2\pi^2\alpha t/L^2}\sin\frac{n\,\pi\,x}{L}\right]$$

An alternate transformation is [41, p. 139], [44, p. 310]

$$T\ (x,t) = T_0 \sum_{n=0}^{\infty}\left[\mathrm{erf}\left(\frac{(2\,n+1)\ L+x}{\sqrt{4\,\alpha\,t}}\right) - \mathrm{erf}\left(\frac{(2\,n+1)\ L-x}{\sqrt{4\,\alpha\,t}}\right)\right]$$

Problem 8. Finite domain, boundary condition of the second kind

$$T\,(x,0) = T_0$$

$$\frac{\partial T}{\partial x}\,(0,t) = 0, T\ (L,t) = 0$$

Take the Laplace transform

$$s\,t\ (x,s) - T_0 = \alpha\,\tfrac{\partial^2 t}{\partial x^2}$$

$$\tfrac{\partial t}{\partial x}\,(0,s) = 0, t\ (L,s) = 0$$

The solution is

$$t\ (x,s) = \frac{T_0}{s}\left[1 - \frac{\cosh x\,\sqrt{s/\alpha}}{\cosh L\,\sqrt{s/\alpha}}\right]$$

Its inverse is [41, p. 138]

$$T\ (x,t) = T_0 - T_0 \sum_{n=0}^{\infty}(-1)^n\left[\mathrm{erfc}\left(\frac{(2n+1)\ L-x}{\sqrt{4\,\alpha\,t}}\right) + \mathrm{erfc}\left(\frac{(2n+1)\ L+x}{\sqrt{4\,\alpha\,t}}\right)\right]$$

5. Vector Analysis

Notation. A *scalar* is a quantity having magnitude but no direction (e.g., mass, length, time, temperature, and concentration). A *vector* is a quantity having both magnitude and direction (e.g., displacement, velocity, acceleration, force). A second-order *dyadic* has magnitude and two directions associated with it, as defined precisely below. The most common examples are the stress dyadic (or tensor) and the velocity gradient (in fluid flow). Vectors are printed in boldface type and identified in this chapter by lower-case Latin letters. Second-order dyadics are printed in boldface type and are identified in this chapter by capital or Greek letters. Higher order dyadics are not discussed here. Dyadics can be formed from the components of tensors including their directions, and some of the identities for dyadics are more easily proved by using tensor analysis, which is not presented here (see also, → Transport Phenomena, Chap. 1.1.4). Vectors are also first-order dyadics.

Vectors. Two vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ are equal if they have the same magnitude and direction. If they have the same magnitude but the opposite direction, then $\boldsymbol{u} = -\boldsymbol{v}$. The sum of two vectors is identified geometrically by placing the vector $\boldsymbol{v}$ at the end of the vector $\boldsymbol{u}$, as shown in Figure 12. The product of a scalar m and a vector $\boldsymbol{u}$ is a vector $m\,\boldsymbol{u}$ in the same direction as $\boldsymbol{u}$ but with a magnitude that equals the magnitude of $\boldsymbol{u}$ times the scalar m. Vectors obey commutative and associative laws.

$\boldsymbol{u} + \boldsymbol{v} = \boldsymbol{v} + \boldsymbol{u}$	Commutative law for addition
$\boldsymbol{u} + (\boldsymbol{v} + \boldsymbol{w}) = (\boldsymbol{u} + \boldsymbol{v}) + \boldsymbol{w}$	Associative law for addition
$m\,\boldsymbol{u} = \boldsymbol{u}\,m$	Commutative law for scalar multiplication
$m\,(n\,\boldsymbol{u}) = (m\,n)\,\boldsymbol{u}$	Associative law for scalar multiplication
$(m + n)\,\boldsymbol{u} = m\,\boldsymbol{u} + n\,\boldsymbol{u}$	Distributive law
$m\,(\boldsymbol{u} + \boldsymbol{v}) = m\,\boldsymbol{u} + m\,\boldsymbol{v}$	Distributive law

The same laws are obeyed by dyadics, as well.

Figure 12. Addition of vectors

A unit vector is a vector with magnitude 1.0 and some direction. If a vector has some magnitude (i.e., not zero magnitude), a unit vector $\boldsymbol{e}_u$ can be formed by

$$\boldsymbol{e}_u = \frac{\boldsymbol{u}}{|\boldsymbol{u}|}$$

The original vector can be represented by the product of the magnitude and the unit vector.

$$\boldsymbol{u} = |\boldsymbol{u}|\,\boldsymbol{e}_u$$

In a cartesian coordinate system the three principle, orthogonal directions are customarily represented by *unit vectors*, such as $\{\boldsymbol{e}_x, \boldsymbol{e}_y, \boldsymbol{e}_z\}$ or $\{\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}\}$. Here, the first notation is used (see Fig. 13). The coordinate system is right handed; that is, if a right-threaded screw rotated from the x to the y direction, it would advance in the z direction. A vector can be represented in terms of its components in these directions, as illustrated in Figure 14. The vector is then written as

$$\boldsymbol{u} = u_x\boldsymbol{e}_x + u_y\boldsymbol{e}_y + u_z\boldsymbol{e}_z$$

The magnitude is

$$|\boldsymbol{u}| = \sqrt{u_x^2 + u_y^2 + u_z^2}$$

The position vector is

$$\boldsymbol{r} = x\boldsymbol{e}_x + y\boldsymbol{e}_y + z\boldsymbol{e}_z$$

with magnitude

$$|\boldsymbol{r}| = \sqrt{x^2 + y^2 + z^2}$$

Figure 13. Cartesian coordinate system

Figure 14. Vector components

Dyadics. The dyadic $\boldsymbol{A}$ is written in component form in cartesian coordinates as

$$\boldsymbol{A} = A_{xx}\boldsymbol{e}_x\boldsymbol{e}_x + A_{xy}\boldsymbol{e}_x\boldsymbol{e}_y + A_{xz}\boldsymbol{e}_x\boldsymbol{e}_z$$

$$+ A_{yx}\boldsymbol{e}_y\boldsymbol{e}_x + A_{yy}\boldsymbol{e}_y\boldsymbol{e}_y + A_{yz}\boldsymbol{e}_y\boldsymbol{e}_z$$

$$+ A_{zx}\boldsymbol{e}_z\boldsymbol{e}_x + A_{zy}\boldsymbol{e}_z\boldsymbol{e}_y + A_{zz}\boldsymbol{e}_z\boldsymbol{e}_z$$

Quantities such as $\boldsymbol{e}_x\boldsymbol{e}_y$ are called *unit dyadics*. They are second-order dyadics and have two directions associated with them, $\boldsymbol{e}_x$ and $\boldsymbol{e}_y$; the order of the pair is important. The components $A_{xx}, \ldots, A_{zz}$ are the components of the tensor A_{ij} which here is a 3×3 matrix of numbers that are transformed in a certain way when variables undergo a linear transformation. The $y\,x$ momentum flux can be defined as the flux of x momentum across an area with unit normal in the y direction (→ Fluid Mechanics, Chap. 2.2; introduction to → Transport Phenomena). Since two directions are involved, a second-order dyadic (or tensor) is needed to represent it, and because the y momentum across an area with unit normal in the x direction may not be the same thing, the order of the indices must be kept straight. The dyadic $\boldsymbol{A}$ is said to be symmetric if

$$\boldsymbol{A}_{ij} = \boldsymbol{A}_{ji}$$

Here, the indices i and j can take the values x, y, or z; sometimes (x, 1), (y, 2), (x, 3) are identified and the indices take the values 1, 2, or 3. The dyadic $\boldsymbol{A}$ is said to be antisymmetric if

$$\boldsymbol{A}_{ij} = -\boldsymbol{A}_{ji}$$

The transpose of $\boldsymbol{A}$ is

$$\boldsymbol{A}_{ij}^{\mathrm{T}} = \boldsymbol{A}_{ji}$$

Any dyadic can be represented as the sum of a symmetric portion and an antisymmetric portion.

$$\boldsymbol{A}_{ij} = \boldsymbol{B}_{ij} + \boldsymbol{C}_{ij}, \boldsymbol{B}_{ij} \equiv \tfrac{1}{2}\left(\boldsymbol{A}_{ij} + \boldsymbol{A}_{ji}\right),$$

$$\boldsymbol{C}_{ij} \equiv \tfrac{1}{2}\left(\boldsymbol{A}_{ij} - \boldsymbol{A}_{ji}\right)$$

An ordered pair of vectors is a second-order dyadic.

$$\boldsymbol{u}\,\boldsymbol{v} = \sum_i \sum_j \boldsymbol{e}_{\mathrm{i}} \boldsymbol{e}_{\mathrm{j}} u_i\, v_j$$

The transpose of this is

$$(\boldsymbol{u}\,\boldsymbol{v})^{\mathrm{T}} = \boldsymbol{v}\,\boldsymbol{u}$$

but

$$\boldsymbol{u}\,\boldsymbol{v} \neq \boldsymbol{v}\,\boldsymbol{u}$$

The Kronecker delta is defined as

$$\delta_{ij} = \left\{ \begin{array}{l} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{array} \right\}$$

and the unit dyadic is defined as

$$\delta = \sum_i \sum_j \boldsymbol{e}_i \boldsymbol{e}_j\, \delta_{ij}$$

Operations. The *dot* or *scalar product* of two vectors is defined as

$$\boldsymbol{u} \cdot \boldsymbol{v} = |\boldsymbol{u}|\,|\boldsymbol{v}| \cos\theta,\ 0 \leq \theta \leq \pi$$

where θ is the angle between $\boldsymbol{u}$ *and* $\boldsymbol{v}$. The scalar product of two vectors is a scalar, not a vector. It is the magnitude of $\boldsymbol{u}$ multiplied by the projection of $\boldsymbol{v}$ on $\boldsymbol{u}$, or vice versa. The scalar product of $\boldsymbol{u}$ with itself is just the square of the magnitude of $\boldsymbol{u}$.

$$\boldsymbol{u} \cdot \boldsymbol{u} = \left|\boldsymbol{u}^2\right| = u^2$$

The following laws are valid for scalar products

$\boldsymbol{u} \cdot \boldsymbol{v} = \boldsymbol{v} \cdot \boldsymbol{u}$	Commutative law for scalar products
$\boldsymbol{u} \cdot (\boldsymbol{v} + \boldsymbol{w}) = \boldsymbol{u} \cdot \boldsymbol{v} + \boldsymbol{u} \cdot \boldsymbol{w}$	Distributive law for scalar products
$\boldsymbol{e}_x \cdot \boldsymbol{e}_x = \boldsymbol{e}_y \cdot \boldsymbol{e}_y = \boldsymbol{e}_z \cdot \boldsymbol{e}_z = 1$	
$\boldsymbol{e}_x \cdot \boldsymbol{e}_y = \boldsymbol{e}_x \cdot \boldsymbol{e}_z = \boldsymbol{e}_y \cdot \boldsymbol{e}_z = 0$	

If the two vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ are written in component notation, the scalar product is

$$\boldsymbol{u} \cdot \boldsymbol{v} = u_x\, v_x + u_y\, v_y + u_z\, v_z$$

If $\boldsymbol{u} \cdot \boldsymbol{v} = 0$ and $\boldsymbol{u}$ and $\boldsymbol{v}$ are not null vectors, then $\boldsymbol{u}$ and $\boldsymbol{v}$ are perpendicular to each other and $\theta = \pi/2$.

The *single dot product* of two dyadics is

$$\boldsymbol{A} \cdot \boldsymbol{B} = \sum_i \sum_j \boldsymbol{e}_i \boldsymbol{e}_j \left(\sum_k A_{ik}\, B_{kj}\right)$$

The *double dot product* of two dyadics is

$$\boldsymbol{A} : \boldsymbol{B} = \sum_i \sum_j A_{ij}\, B_{ji}$$

Because the dyadics may not be symmetric, the order of indices and which indices are summed are important. The order is made clearer when the dyadics are made from vectors.

$$(\boldsymbol{u}\,\boldsymbol{v}) \cdot (\boldsymbol{w}\,\boldsymbol{x}) = \boldsymbol{u}\,(\boldsymbol{v} \cdot \boldsymbol{w})\,\boldsymbol{x} = \boldsymbol{u}\,\boldsymbol{x}\,(\boldsymbol{v} \cdot \boldsymbol{w})$$

$$(\boldsymbol{u}\,\boldsymbol{v}) : (\boldsymbol{w}\,\boldsymbol{x}) = (\boldsymbol{u} \cdot \boldsymbol{x})\,(\boldsymbol{v} \cdot \boldsymbol{w})$$

The dot product of a dyadic and a vector is

$$\boldsymbol{A} \cdot \boldsymbol{u} = \sum_i \boldsymbol{e}_i \left(\sum_j A_{ij}\, u_j\right)$$

The *cross* or *vector product* is defined by

$$\boldsymbol{c} = \boldsymbol{u} \times \boldsymbol{v} = \boldsymbol{a}\,|u|\,|v| \sin\theta,\ 0 \leq \theta \leq \pi$$

where $\boldsymbol{a}$ is a unit vector in the direction of $\boldsymbol{u} \times \boldsymbol{v}$. The direction of $\boldsymbol{c}$ is perpendicular to the plane of $\boldsymbol{u}$ and $\boldsymbol{v}$ such that $\boldsymbol{u}$, $\boldsymbol{v}$, and $\boldsymbol{c}$ form a right-handed system. If $\boldsymbol{u} = \boldsymbol{v}$, or $\boldsymbol{u}$ is parallel to $\boldsymbol{v}$, then $\theta = 0$ and $\boldsymbol{u} \times \boldsymbol{v} = 0$. The following laws are valid for cross products.

$\boldsymbol{u} \times \boldsymbol{v} = -\boldsymbol{v} \times \boldsymbol{u}$	Commutative law fails for vector product
$\boldsymbol{u} \times (\boldsymbol{v} \times \boldsymbol{w}) \neq (\boldsymbol{u} \times \boldsymbol{v}) \times \boldsymbol{w}$	Associative law fails for vector product
$\boldsymbol{u} \times (\boldsymbol{v} + \boldsymbol{w}) = \boldsymbol{u} \times \boldsymbol{v} + \boldsymbol{u} \times \boldsymbol{w}$	Distributive law for vector product
$\boldsymbol{e}_x \times \boldsymbol{e}_x = \boldsymbol{e}_y \times \boldsymbol{e}_y = \boldsymbol{e}_z \times \boldsymbol{e}_z = 0$	
$\boldsymbol{e}_x \times \boldsymbol{e}_y = \boldsymbol{e}_z,\ \boldsymbol{e}_y \times \boldsymbol{e}_z = \boldsymbol{e}_x,\ \boldsymbol{e}_z \times \boldsymbol{e}_x = \boldsymbol{e}_y$	

$$\boldsymbol{u} \times \boldsymbol{v} = \det \begin{bmatrix} \boldsymbol{e}_x & \boldsymbol{e}_y & \boldsymbol{e}_z \\ u_x & u_y & u_z \\ v_x & v_y & v_z \end{bmatrix}$$

$$= \boldsymbol{e}_x\,(u_y\, v_z - v_y\, u_z) + e_y\,(u_z\, v_z - u_x\, v_z)$$

$$+ \boldsymbol{e}_z\,(u_x\, v_y - u_y\, v_x)$$

This can also be written as

$$\boldsymbol{u}\times\boldsymbol{v} = \sum_i \sum_j \varepsilon_{kij}\, u_i\, v_j \boldsymbol{e}_k$$

where

$$\varepsilon_{ijk} = \begin{cases} 1 & \text{if } i,j,k \text{ is an even permutation of } 123 \\ -1 & \text{if } i,j,k \text{ is an odd permutation of } 123 \\ 0 & \text{if any two of } i,j,k \text{ are equal} \end{cases}$$

Thus ε_{123} = 1, ε_{132} =- 1, ε_{312} = 1, ε_{112} = 0, for example.

The magnitude of $\boldsymbol{u}\times\boldsymbol{v}$ is the same as the area of a parallelogram with sides $\boldsymbol{u}$ and $\boldsymbol{v}$. If $\boldsymbol{u}\times\boldsymbol{v}$ = $\boldsymbol{0}$ and $\boldsymbol{u}$ *and* $\boldsymbol{v}$ are not null vectors, then $\boldsymbol{u}$ *and* $\boldsymbol{v}$ are parallel. Certain triple products are useful.

$$(\boldsymbol{u}\cdot\boldsymbol{v})\,\boldsymbol{w} \neq \boldsymbol{u}\,(\boldsymbol{v}\cdot\boldsymbol{w})$$

$$\boldsymbol{u}\cdot(\boldsymbol{v}\times\boldsymbol{w}) = \boldsymbol{v}\cdot(\boldsymbol{w}\times\boldsymbol{u}) = \boldsymbol{w}\cdot(\boldsymbol{u}\times\boldsymbol{v})$$

$$\boldsymbol{u}\times(\boldsymbol{v}\times\boldsymbol{w}) = (\boldsymbol{u}\cdot\boldsymbol{w})\,v - (\boldsymbol{u}\cdot\boldsymbol{v})\,\boldsymbol{w}$$

$$(\boldsymbol{u}\times\boldsymbol{v})\times\boldsymbol{w} = (\boldsymbol{u}\cdot\boldsymbol{w})\,v - (\boldsymbol{v}\cdot\boldsymbol{w})\,\boldsymbol{u}$$

The cross product of a dyadic and a vector is defined as

$$\boldsymbol{A}\times\boldsymbol{u} = \sum_i \sum_j \boldsymbol{e}_i \boldsymbol{e}_j \left(\sum_k \sum_l \varepsilon_{klj}\, A_{ik}\, u_l\right)$$

The magnitude of a dyadic is

$$|\boldsymbol{A}| = A = \sqrt{\frac{1}{2}\,(\boldsymbol{A}{:}\boldsymbol{A}^{\mathrm{T}})} = \sqrt{\frac{1}{2}\sum_i \sum_j A_{ij}^2}$$

There are three *invariants* of a dyadic. They are called invariants because they take the same value in any coordinate system and are thus an intrinsic property of the dyadic. They are the trace of $\boldsymbol{A}, \boldsymbol{A}^2, \boldsymbol{A}^3$ [45].

$$\mathrm{I} = \mathrm{tr}\boldsymbol{A} = \sum_i A_{ii}$$

$$\mathrm{II} = \mathrm{tr}\boldsymbol{A}^2 = \sum_i \sum_j A_{ij}\, A_{ji}$$

$$\mathrm{III} = \mathrm{tr}\boldsymbol{A}^3 = \sum_i \sum_j \sum_k A_{ij}\, A_{jk}\, A_{ki}$$

The invariants can also be expressed as

$$\mathrm{I}_1 = \mathrm{I}$$

$$\mathrm{I}_2 = \tfrac{1}{2}\,\left(\mathrm{I}^2 - \mathrm{II}\right)$$

$$\mathrm{I}_3 = \tfrac{1}{6}\,\left(\mathrm{I}^3 - 3\,\mathrm{I}\cdot\mathrm{II} + 2\,\mathrm{III}\right) = \det \boldsymbol{A}$$

Invariants of two dyadics are available [46]. Because a second-order dyadic has nine components, the *characteristic equation*

$$\det\,(\lambda\,\boldsymbol{\delta} - \boldsymbol{A}) = 0$$

can be formed where λ is an eigenvalue. This expression is

$$\lambda^3 - I_1\lambda^2 + I_2\lambda - I_3 = 0$$

An important theorem of Hamilton and Cayley [47] is that a second-order dyadic satisfies its own characteristic equation.

$$\boldsymbol{A}^3 - I_1\boldsymbol{A}^2 + I_2\boldsymbol{A} - I_3\boldsymbol{\delta} = 0 \tag{7}$$

Thus $\boldsymbol{A}^3$ can be expressed in terms of $\boldsymbol{\delta}$, $\boldsymbol{A}$, and $\boldsymbol{A}^2$. Similarly, higher powers of $\boldsymbol{A}$ can be expressed in terms of $\boldsymbol{\delta}$, $\boldsymbol{A}$, and $\boldsymbol{A}^2$. Decomposition of a dyadic into a symmetric and an antisymmetric part was shown above. The antisymmetric part has zero trace. The symmetric part can be decomposed into a part with a trace (the isotropic part) and a part with zero trace (the deviatoric part).

$$\boldsymbol{A} = \underbrace{1/3\,\boldsymbol{\delta}\boldsymbol{\delta}:\boldsymbol{A}}_{\text{Isotropic}} + \underbrace{1/2\,[\boldsymbol{A} + \boldsymbol{A}^{\mathrm{T}} - 2/3\,\boldsymbol{\delta}\boldsymbol{\delta}:\boldsymbol{A}]}_{\text{Deviatoric}} + \underbrace{1/2\,[\boldsymbol{A} - \boldsymbol{A}^{\mathrm{T}}]}_{\text{Antisymmetric}}$$

Differentiation. The derivative of a vector is defined in the same way as the derivative of a scalar. Suppose the vector $\boldsymbol{u}$ depends on t. Then

$$\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} = \lim_{\Delta t\to 0} \frac{\boldsymbol{u}\,(t+\Delta t) - \boldsymbol{u}\,(t)}{\Delta t}$$

If the vector is the position vector $\boldsymbol{r}\,(t)$, then the difference expression is a vector in the direction of $\Delta\,\boldsymbol{r}$ (see Fig. 15). The derivative

$$\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t} = \lim_{\Delta t\to 0} \frac{\Delta\boldsymbol{r}}{\Delta t} = \lim_{\Delta t\to 0} \frac{\boldsymbol{r}\,(t+\Delta t) - \boldsymbol{r}\,(t)}{\Delta t}$$

is the velocity. The derivative operation obeys the following laws.

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\,(\boldsymbol{u}+\boldsymbol{v}) = \tfrac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} + \tfrac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}$$

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\,(\boldsymbol{u}\cdot\boldsymbol{v}) = \tfrac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}\cdot\boldsymbol{v} + \boldsymbol{u}\cdot\tfrac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}$$

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\,(\boldsymbol{u}\times\boldsymbol{v}) = \tfrac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}\times\boldsymbol{v} + \boldsymbol{u}\times\tfrac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}$$

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\,(\varphi\boldsymbol{u}) = \tfrac{\mathrm{d}\varphi}{\mathrm{d}t}\boldsymbol{u} + \varphi\tfrac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}$$

If the vector $\boldsymbol{u}$ depends on more than one variable, such as x, y and z, partial derivatives are defined in the usual way. For example,

$$\text{if } \boldsymbol{u}\,(x, y, z)\text{, then}$$

$$\frac{\partial\boldsymbol{u}}{\partial x} = \lim_{\Delta t\to 0} \frac{\boldsymbol{u}(x+\Delta x,\, y,\, z) - \boldsymbol{u}(x,\, y,\, z)}{\Delta x}$$

Rules for differentiation of scalar and vector products are

$$\frac{\partial}{\partial x}(\boldsymbol{u}\cdot\boldsymbol{v}) = \frac{\partial \boldsymbol{u}}{\partial x}\cdot\boldsymbol{v}+\boldsymbol{u}\cdot\frac{\partial \boldsymbol{v}}{\partial x}$$

$$\frac{\partial}{\partial x}(\boldsymbol{u}\times\boldsymbol{v}) = \frac{\partial \boldsymbol{u}}{\partial x}\times\boldsymbol{v}+\boldsymbol{u}\times\frac{\partial \boldsymbol{v}}{\partial x}$$

Differentials of vectors are

$$\mathrm{d}\boldsymbol{u} = \mathrm{d}u_x\boldsymbol{e}_x+\mathrm{d}u_y\boldsymbol{e}_y+\mathrm{d}u_z\boldsymbol{e}_z$$

$$\mathrm{d}(\boldsymbol{u}\cdot\boldsymbol{v}) = \mathrm{d}\boldsymbol{u}\cdot\boldsymbol{v}+\boldsymbol{u}\cdot\mathrm{d}\boldsymbol{v}$$

$$\mathrm{d}(\boldsymbol{u}\times\boldsymbol{v}) = \mathrm{d}\boldsymbol{u}\times\boldsymbol{v}+\boldsymbol{u}\times\mathrm{d}\boldsymbol{v}$$

$$\mathrm{d}\boldsymbol{u} = \frac{\partial \boldsymbol{u}}{\partial x}\mathrm{d}x+\frac{\partial \boldsymbol{u}}{\partial y}\mathrm{d}y+\frac{\partial \boldsymbol{u}}{\partial z}\mathrm{d}z$$

Figure 15. Vector differentiation

If a curve is given by $\boldsymbol{r}(t)$, the length of the curve is [43]

$$L = \int_a^b \sqrt{\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t}\cdot\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t}}\,\mathrm{d}t$$

The arc-length function can also be defined:

$$s(t) = \int_a^t \sqrt{\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t^*}\cdot\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t^*}}\,\mathrm{d}t^*$$

This gives

$$\left(\frac{\mathrm{d}s}{\mathrm{d}t}\right)^2 = \frac{\mathrm{d}r}{\mathrm{d}t}\cdot\frac{\mathrm{d}r}{\mathrm{d}t} = \left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+\left(\frac{\mathrm{d}y}{\mathrm{d}t}\right)^2+\left(\frac{\mathrm{d}z}{\mathrm{d}t}\right)^2$$

Because

$$d\boldsymbol{r} = \mathrm{d}x\boldsymbol{e}_x+\mathrm{d}y\boldsymbol{e}_y+\mathrm{d}z\boldsymbol{e}_z$$

then

$$ds^2 = \mathrm{d}\boldsymbol{r}\cdot\mathrm{d}\boldsymbol{r} = \mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2$$

The derivative d$\boldsymbol{r}$/dt is tangent to the curve in the direction of motion

$$\boldsymbol{u} = \frac{\frac{\mathrm{d}r}{\mathrm{d}t}}{\left|\frac{\mathrm{d}r}{\mathrm{d}t}\right|}$$

Also,

$$\boldsymbol{u} = \frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s}$$

Differential Operators (see also, → Transport Phenomena, Chap. 1.1.4). The vector differential operator (del operator) $\boldsymbol{\nabla}$ is defined in cartesian coordinates by

$$\boldsymbol{\nabla} = \boldsymbol{e}_x\frac{\partial}{\partial x}+\boldsymbol{e}_y\frac{\partial}{\partial y}+\boldsymbol{e}_z\frac{\partial}{\partial z}$$

The *gradient* of a scalar function is defined

$$\boldsymbol{\nabla}\varphi = \boldsymbol{e}_x\frac{\partial\varphi}{\partial x}+\boldsymbol{e}_y\frac{\partial\varphi}{\partial y}+\boldsymbol{e}_z\frac{\partial\varphi}{\partial z}$$

and is a vector. If φ is height or elevation, the gradient is a vector pointing in the uphill direction. The steeper the hill, the larger is the magnitude of the gradient.

The *divergence* of a vector is defined by

$$\boldsymbol{\nabla}\cdot\boldsymbol{u} = \frac{\partial u_x}{\partial x}+\frac{\partial u_y}{\partial y}+\frac{\partial u_z}{\partial z}$$

and is a scalar. For a volume element ΔV, the net outflow of a vector $\boldsymbol{u}$ over the surface of the element is

$$\int_{\Delta S}\boldsymbol{u}\cdot\boldsymbol{n}\mathrm{d}S$$

This is related to the divergence by [48, p. 411]

$$\boldsymbol{\nabla}\cdot\boldsymbol{u} = \lim_{\Delta V\to 0}\frac{1}{\Delta V}\int_{\Delta S}\boldsymbol{u}\cdot\boldsymbol{n}\mathrm{d}S$$

Thus, the divergence is the net outflow per unit volume.

The *curl* of a vector is defined by

$$\boldsymbol{\nabla}\times\boldsymbol{u} = \left(\boldsymbol{e}_x\frac{\partial}{\partial x}+\boldsymbol{e}_y\frac{\partial}{\partial y}+\boldsymbol{e}_z\frac{\partial}{\partial z}\right)$$

$$\times(\boldsymbol{e}_x u_x+\boldsymbol{e}_y u_y+\boldsymbol{e}_z u_z)$$

$$= \boldsymbol{e}_x\left(\frac{\partial u_z}{\partial y}-\frac{\partial u_y}{\partial z}\right)+\boldsymbol{e}_y\left(\frac{\partial u_x}{\partial z}-\frac{\partial u_z}{\partial x}\right)$$

$$+\boldsymbol{e}_z\left(\frac{\partial u_y}{\partial x}-\frac{\partial u_x}{\partial y}\right)$$

and is a vector. It is related to the integral

$$\int_C \boldsymbol{u}\cdot\mathrm{d}\boldsymbol{s} = \int_C u_s\mathrm{d}s$$

which is called the circulation of $\boldsymbol{u}$ around path C. This integral depends on the vector and the contour C, in general. If the circulation does not depend on the contour C, the vector is said to be irrotational; if it does, it is rotational. The relationship with the curl is [48, p. 419]

$$\boldsymbol{n}\cdot(\boldsymbol{\nabla}\times\boldsymbol{u}) = \lim_{\Delta\to 0}\frac{1}{\Delta S}\int_C \boldsymbol{u}\cdot\mathrm{d}\boldsymbol{s}$$

Thus, the normal component of the curl equals the net circulation per unit area enclosed by the contour C.

The gradient, divergence, and curl obey a distributive law but not a commutative or associative law.

$$\boldsymbol{\nabla}(\varphi+\psi) = \boldsymbol{\nabla}\varphi+\boldsymbol{\nabla}\psi$$

$$\boldsymbol{\nabla}\cdot(\boldsymbol{u}+\boldsymbol{v}) = \boldsymbol{\nabla}\cdot\boldsymbol{u}+\boldsymbol{\nabla}\cdot\boldsymbol{v}$$

$$\boldsymbol{\nabla}\times(\boldsymbol{u}+\boldsymbol{v}) = \boldsymbol{\nabla}\times\boldsymbol{u}+\boldsymbol{\nabla}\times\boldsymbol{v}$$

$$\boldsymbol{\nabla}\cdot\varphi\neq\varphi\boldsymbol{\nabla}$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{u}\neq\boldsymbol{u}\cdot\boldsymbol{\nabla}$$

Useful formulas are [49]

$$\boldsymbol{\nabla}\cdot(\varphi\boldsymbol{u}) = \boldsymbol{\nabla}\varphi\cdot\boldsymbol{u}+\varphi\boldsymbol{\nabla}\cdot\boldsymbol{u}$$

$$\boldsymbol{\nabla}\times(\varphi\boldsymbol{u}) = \boldsymbol{\nabla}\varphi\times\boldsymbol{u}+\varphi\boldsymbol{\nabla}\times\boldsymbol{u}$$

$$\boldsymbol{\nabla}\cdot(\boldsymbol{u}\times\boldsymbol{v}) = \boldsymbol{v}\cdot(\boldsymbol{\nabla}\times\boldsymbol{u})-\boldsymbol{u}\cdot(\boldsymbol{\nabla}\times\boldsymbol{v})$$

$$\boldsymbol{\nabla}\times(\boldsymbol{u}\times\boldsymbol{v}) = \boldsymbol{v}\cdot\boldsymbol{\nabla}\boldsymbol{u}-\boldsymbol{v}(\boldsymbol{\nabla}\cdot\boldsymbol{u})-\boldsymbol{u}\cdot\boldsymbol{\nabla}\boldsymbol{v}+\boldsymbol{u}(\boldsymbol{\nabla}\cdot\boldsymbol{v})$$

$$\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\boldsymbol{u}) = \boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\boldsymbol{u})-\nabla^2\boldsymbol{u}$$

$$\boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\varphi) = \nabla^2\varphi = \frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial y^2}+\frac{\partial^2\varphi}{\partial z^2}, \text{ where } \nabla^2$$

is called the Laplacian operator. $\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\varphi) = \boldsymbol{0}$. The curl of the gradient of φ is zero.

$$\boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\times\boldsymbol{u}) = 0$$

The divergence of the curl of $\boldsymbol{u}$ is zero. Formulas useful in fluid mechanics are

$$\boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\boldsymbol{v})^{\mathrm{T}} = \boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\boldsymbol{v})$$

$$\boldsymbol{\nabla}\cdot(\tau\cdot\boldsymbol{v}) = \boldsymbol{v}\cdot(\boldsymbol{\nabla}\cdot\tau)+\tau:\boldsymbol{\nabla}\boldsymbol{v}$$

$$\boldsymbol{v}\cdot\boldsymbol{\nabla}\boldsymbol{v} = \tfrac{1}{2}\boldsymbol{\nabla}(\boldsymbol{v}\cdot\boldsymbol{v})-\boldsymbol{v}\times(\boldsymbol{\nabla}\times\boldsymbol{v})$$

If a coordinate system is transformed by a rotation and translation, the coordinates in the new system (denoted by primes) are given by

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} l_{11} & l_{12} & l_{13} \\ l_{21} & l_{22} & l_{23} \\ l_{31} & l_{32} & l_{33} \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix}$$

Any function that has the same value in all coordinate systems is an invariant. The gradient of an invariant scalar field is invariant; the same is true for the divergence and curl of invariant vectors fields.

The gradient of a vector field is required in fluid mechanics because the velocity gradient is used. It is defined as

$$\boldsymbol{\nabla}\boldsymbol{v} = \sum_i\sum_j \boldsymbol{e}_i\boldsymbol{e}_j\frac{\partial v_j}{\partial x_i} \text{ and}$$

$$(\boldsymbol{\nabla}\boldsymbol{v})^{\mathrm{T}} = \sum_i\sum_j \boldsymbol{e}_i\boldsymbol{e}_j\frac{\partial v_i}{\partial x_j}$$

The divergence of dyadics is defined

$$\boldsymbol{\nabla}\cdot\boldsymbol{\tau} = \sum_i \boldsymbol{e}_i\left(\sum_j\frac{\partial\tau_{ji}}{\partial x_j}\right) \text{ and}$$

$$\boldsymbol{\nabla}\cdot(\varphi\boldsymbol{u}\,\boldsymbol{v}) = \sum_i \boldsymbol{e}_i\left[\sum_j\frac{\partial}{\partial x_j}(\varphi u_j\,v_i)\right]$$

where $\boldsymbol{\tau}$ is any second-order dyadic.

Useful relations involving dyadics are

$$(\varphi\,\boldsymbol{\delta}:\boldsymbol{\nabla}\boldsymbol{v}) = \varphi(\boldsymbol{\nabla}\cdot\boldsymbol{v})$$

$$\boldsymbol{\nabla}\cdot(\varphi\,\boldsymbol{\delta}) = \boldsymbol{\nabla}\varphi$$

$$\boldsymbol{\nabla}\cdot(\varphi\boldsymbol{\tau}) = \boldsymbol{\nabla}\varphi\cdot\boldsymbol{\tau}+\varphi\boldsymbol{\nabla}\cdot\boldsymbol{\tau}$$

$$\boldsymbol{n}\,\boldsymbol{t}:\boldsymbol{\tau} = \boldsymbol{t}\cdot\boldsymbol{\tau}\cdot\boldsymbol{n} = \boldsymbol{\tau}:\boldsymbol{n}\,\boldsymbol{t}$$

A surface can be represented in the form

$$f\,(x,y,z) = c = \text{ constant}$$

The normal to the surface is given by

$$\boldsymbol{n} = \frac{\boldsymbol{\nabla}f}{|\boldsymbol{\nabla}f|}$$

provided the gradient is not zero. Operations can be performed entirely within the surface. Define

$$\boldsymbol{\delta}_{\mathrm{II}}\equiv\boldsymbol{\delta}-\boldsymbol{n}\,\boldsymbol{n}, \boldsymbol{\nabla}_{\mathrm{II}}\equiv\boldsymbol{\delta}_{\mathrm{II}}\cdot\boldsymbol{\nabla}, \frac{\partial}{\partial n}\equiv\boldsymbol{n}\cdot\boldsymbol{\nabla}$$

$$\boldsymbol{v}_{\mathrm{II}}\equiv\boldsymbol{\delta}_{\mathrm{II}}\cdot\boldsymbol{v}, v_n\equiv\boldsymbol{n}\cdot\boldsymbol{v}$$

Then a vector and del operator can be decomposed into

$$\boldsymbol{v} = \boldsymbol{v}_{\mathrm{II}}+\boldsymbol{n}v_n, \boldsymbol{\nabla} = \boldsymbol{\nabla}_{\mathrm{II}}+\boldsymbol{n}\frac{\partial}{\partial n}$$

The velocity gradient can be decomposed into

$$\boldsymbol{\nabla}\boldsymbol{v} = \boldsymbol{\nabla}_{\mathrm{II}}\boldsymbol{v}_{\mathrm{II}}+(\boldsymbol{\nabla}_{\mathrm{II}}\boldsymbol{n})\,v_n+\boldsymbol{n}\boldsymbol{\nabla}_{\mathrm{II}}v_n+\boldsymbol{n}\frac{\partial\boldsymbol{v}_{\mathrm{II}}}{\partial n}+\boldsymbol{n}\,\boldsymbol{n}\frac{\partial v_n}{\partial n}$$

The surface gradient of the normal is the negative of the curvature dyadic of the surface.

$$\boldsymbol{\nabla}_{\mathrm{II}}\boldsymbol{n} = -\boldsymbol{B}$$

The surface divergence is then

$$\boldsymbol{\nabla}_{\mathrm{II}}\cdot\boldsymbol{v} = \boldsymbol{\delta}_{\mathrm{II}}:\boldsymbol{\nabla}\boldsymbol{v} = \boldsymbol{\nabla}_{\mathrm{II}}\cdot\boldsymbol{v}_{\mathrm{II}}-2\,H\,v_n$$

where H is the mean curvature.

$$H = \frac{1}{2}\boldsymbol{\delta}_{\mathrm{II}} : \boldsymbol{B}$$

The surface curl can be a scalar

$$\boldsymbol{\nabla}_{\mathrm{II}} \times \boldsymbol{v} = -\boldsymbol{\varepsilon}_{\mathrm{II}} : \boldsymbol{\nabla}\boldsymbol{v} = -\boldsymbol{\varepsilon}_{\mathrm{II}} : \boldsymbol{\nabla}_{\mathrm{II}}\boldsymbol{v}_{\mathrm{II}} = -\boldsymbol{n} \cdot (\boldsymbol{\nabla} \times \boldsymbol{v}),$$

$$\boldsymbol{\varepsilon}_{\mathrm{II}} = \boldsymbol{n} \cdot \boldsymbol{\varepsilon}$$

or a vector

$$\boldsymbol{\nabla}_{\mathrm{II}} \times \boldsymbol{v} \equiv \boldsymbol{\nabla}_{\mathrm{II}} \times \boldsymbol{v}_{\mathrm{II}} = \boldsymbol{n}\boldsymbol{\nabla}_{\mathrm{II}} \times \boldsymbol{v} = \boldsymbol{n}\,\boldsymbol{n} \cdot \boldsymbol{\nabla} \times v$$

Vector Integration [48, pp. 206 – 212]. If $\boldsymbol{u}$ is a vector, then its integral is also a vector.

$$\int \boldsymbol{u}(t)\,\mathrm{d}t = \boldsymbol{e}_x \int u_x(t)\,\mathrm{d}t + \boldsymbol{e}_y \int u_y(t)\,\mathrm{d}t + \boldsymbol{e}_z \int u_z(t)\,\mathrm{d}t$$

If the vector $\boldsymbol{u}$ is the derivative of another vector, then

$$\boldsymbol{u} = \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}, \int \boldsymbol{u}(t)\,\mathrm{d}t = \int \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}\,\mathrm{d}t = \boldsymbol{v} + \text{constant}$$

If $\boldsymbol{r}(t)$ is a position vector that defines a curve C, the line integral is defined by

$$\int_C \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{r} = \int_C (u_x \mathrm{d}x + u_y \mathrm{d}y + u_z \mathrm{d}z)$$

Theorems about this line integral can be written in various forms.

Theorem [43]. If the functions appearing in the line integral are continuous in a domain D, then the line integral is independent of the path C if and only if the line integral is zero on every simple closed path in D.

Theorem [43]. If $\boldsymbol{u} = \boldsymbol{\nabla}\varphi$ where φ is single-valued and has continuous derivatives in D, then the line integral is independent of the path C and the line integral is zero for any closed curve in D.

Theorem [43]. If f, g, and h are continuous functions of x, y, and z, and have continuous first derivatives in a simply connected domain D, then the line integral

$$\int_C (f\,\mathrm{d}x + g\mathrm{d}y + h\mathrm{d}z)$$

is independent of the path if and only if

$$\frac{\partial h}{\partial y} = \frac{\partial g}{\partial z}, \frac{\partial f}{\partial z} = \frac{\partial h}{\partial x}, \frac{\partial g}{\partial x} = \frac{\partial f}{\partial y}$$

or if f, g, and h are regarded as the x, y, and z components of a vector $\boldsymbol{v}$:

$$\boldsymbol{\nabla} \times \boldsymbol{v} = 0$$

Consequently, the line integral is independent of the path (and the value is zero for a closed contour) if the three components in it are regarded as the three components of a vector and the vector is derivable from a potential (or zero curl). The conditions for a vector to be derivable from a potential are just those in the third theorem. In two dimensions this reduces to the more usual theorem.

Theorem [48, p. 207]. If M and N are continuous functions of x and y that have continuous first partial derivatives in a simply connected domain D, then the necessary and sufficient condition for the line integral

$$\int_C (M\mathrm{d}x + N\mathrm{d}y)$$

to be zero around every closed curve C in D is

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$$

If a vector is integrated over a surface with incremental area $\mathrm{d}S$ and normal to the surface $\boldsymbol{n}$, then the surface integral can be written as

$$\int\int_S \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{S} = \int\int_S \boldsymbol{u} \cdot \boldsymbol{n}\mathrm{d}S$$

If $\boldsymbol{u}$ is the velocity then this integral represents the flow rate past the surface S.

Divergence Theorem [48, 49]. If V is a volume bounded by a closed surface S and $\boldsymbol{u}$ is a vector function of position with continuous derivatives, then

$$\int_V \boldsymbol{\nabla} \cdot \boldsymbol{u}\mathrm{d}V = \int_S \boldsymbol{n} \cdot \boldsymbol{u}\mathrm{d}S = \int_S \boldsymbol{u} \cdot \boldsymbol{n}\mathrm{d}S = \int_S \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{S}$$

where $\boldsymbol{n}$ is the normal pointing outward to S. The normal can be written as

$$\boldsymbol{n} = \boldsymbol{e}_x \cos(x, n) + \boldsymbol{e}_y \cos(y, n) + \boldsymbol{e}_z \cos(z, n)$$

where, for example, cos (x, n) is the cosine of the angle between the normal n and the x axis. Then the divergence theorem in component form is

$$\int_V \left(\frac{\partial u_x}{\partial x} + \frac{\partial u_y}{\partial y} + \frac{\partial u_z}{\partial z}\right) \mathrm{d}x\mathrm{d}y\mathrm{d}z =$$

$$\int_S [u_x \cos(x, n) + u_y \cos(y, n) + u_z \cos(z, n)]\,\mathrm{d}S$$

If the divergence theorem is written for an incremental volume

$$\nabla\cdot\boldsymbol{u} = \lim_{\Delta V\to 0}\frac{1}{\Delta V}\int_{\Delta S} u_n \mathrm{d}S$$

the divergence of a vector can be called the integral of that quantity over the area of a closed volume, divided by the volume. If the vector represents the flow of energy and the divergence is positive at a point *P*, then either a source of energy is present at *P* or energy is leaving the region around *P* so that its temperature is decreasing. If the vector represents the flow of mass and the divergence is positive at a point *P*, then either a source of mass exists at *P* or the density is decreasing at the point *P*. For an incompressible fluid the divergence is zero and the rate at which fluid is introduced into a volume must equal the rate at which it is removed.

Various theorems follow from the divergence theorem.

Theorem. If φ is a solution to Laplace's equation

$$\nabla^2\varphi = 0$$

in a domain D, and the second partial derivatives of φ are continuous in D, then the integral of the normal derivative of φ over any piecewise smooth closed orientable surface *S* in D is zero. Suppose $\boldsymbol{u} = \varphi\,\nabla\psi$ satisfies the conditions of the divergence theorem: then *Green's theorem* results from use of the divergence theorem [49].

$$\int_V \left(\varphi\nabla^2\psi + \nabla\varphi\cdot\nabla\psi\right)\mathrm{d}V = \int_S \varphi\frac{\partial\psi}{\partial n}\mathrm{d}S$$

and

$$\int_V \left(\varphi\nabla^2\psi - \psi\nabla^2\varphi\right)\mathrm{d}V = \int_S \left(\varphi\frac{\partial\psi}{\partial n} - \psi\frac{\partial\varphi}{\partial n}\right)\mathrm{d}S$$

Also if φ satisfies the conditions of the theorem and is zero on *S* then φ is zero throughout D. If two functions φ and ψ both satisfy the Laplace equation in domain D, and both take the same values on the bounding curve *C*, then $\varphi = \psi$; i.e., the solution to the Laplace equation is unique.

The divergence theorem for dyadics is

$$\int_V \nabla\cdot\boldsymbol{\tau}\mathrm{d}V = \int_S \boldsymbol{n}\cdot\boldsymbol{\tau}\,\mathrm{d}S$$

Stokes Theorem [48, 49]. Stokes theorem says that if *S* is a surface bounded by a closed, nonintersecting curve *C*, and if $\boldsymbol{u}$ has continuous derivatives then

$$\oint_C \boldsymbol{u}\cdot\mathrm{d}\boldsymbol{r} = \iint_S (\nabla\times\boldsymbol{u})\cdot\boldsymbol{n}\mathrm{d}S = \iint_S (\nabla\times\boldsymbol{u})\cdot\mathrm{d}\boldsymbol{S}$$

The integral around the curve is followed in the counterclockwise direction. In component notation, this is

$$\oint_C \left[u_x\cos\,(x,s) + u_y\cos\,(y,s) + u_z\cos\,(z,s)\right]\mathrm{d}s =$$
$$\iint_S \left[\left(\frac{\partial u_z}{\partial y} - \frac{\partial u_y}{\partial z}\right)\cos(x,n)\right.$$
$$+\left(\frac{\partial u_x}{\partial z} - \frac{\partial u_z}{\partial x}\right)\cos\,(y,n)$$
$$\left.+\left(\frac{\partial u_y}{\partial x} - \frac{\partial u_x}{\partial y}\right)\cos(z,n)\right]\mathrm{d}S$$

Applied in two dimensions, this results in Green's theorem in the plane:

$$\oint_C (M\mathrm{d}x + N\mathrm{d}y) = \iint_S \left(\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y}\right)\mathrm{d}x\mathrm{d}y$$

The formula for dyadics is

$$\iint_S \boldsymbol{n}\cdot(\nabla\times\boldsymbol{\tau})\,\mathrm{d}S = \oint_C \boldsymbol{\tau}^{\mathrm{T}}\cdot\mathrm{d}\boldsymbol{r}$$

Representation. Two theorems give information about how to represent vectors that obey certain properties.

Theorem [48*, p. 422].* The necessary and sufficient condition that the curl of a vector vanish identically is that the vector be the gradient of some function.

Theorem [48*, p. 423].* The necessary and sufficient condition that the divergence of a vector vanish identically is that the vector is the curl of some other vector.

Leibniz Formula. In fluid mechanics and transport phenomena, an important result is the derivative of an integral whose limits of integration are moving. Suppose the region *V* (*t*) is moving with velocity $\boldsymbol{v}_s$. Then Leibniz's rule holds:

$$\frac{\mathrm{d}}{\mathrm{d}t}\iiint_{V(t)} \varphi\mathrm{d}V = \iiint_{V(t)} \frac{\partial\varphi}{\partial t}\mathrm{d}V + \iint_S \varphi\boldsymbol{v}_s\cdot\boldsymbol{n}\mathrm{d}S$$

Curvilinear Coordinates. Many of the relations given above are proved most easily by using tensor analysis rather than dyadics. Once proven, however, the relations are perfectly general in any coordinate system. Displayed here are the specific results for cylindrical and spherical geometries. Results are available for a few other geometries: parabolic cylindrical, paraboloidal, elliptic cylindrical, prolate spheroidal, oblate spheroidal, ellipsoidal, and bipolar coordinates [45, 50].

For *cylindrical coordinates*, the geometry is shown in Figure 16. The coordinates are related to cartesian coordinates by

Figure 16. Cylindrical coordinate system

$x = r\cos\theta$	$r = \sqrt{x^2+y^2}$
$y = r\sin\theta$	$\theta = \arctan\left(\frac{y}{x}\right)$
$z = z$	$z = z$

The unit vectors are related by

$\boldsymbol{e}_r = \cos\theta\boldsymbol{e}_x + \sin\theta\boldsymbol{e}_y$	$\boldsymbol{e}_x = \cos\theta\boldsymbol{e}_r - \sin\theta\boldsymbol{e}_\theta$
$\boldsymbol{e}_\theta = -\sin\theta\boldsymbol{e}_x + \cos\theta\boldsymbol{e}_y$	$\boldsymbol{e}_y = \sin\theta\boldsymbol{e}_r + \cos\theta\boldsymbol{e}_\theta$
$\boldsymbol{e}_z = \boldsymbol{e}_z$	$\boldsymbol{e}_z = \boldsymbol{e}_z$

Derivatives of the unit vectors are

$$\mathrm{d}\boldsymbol{e}_\theta = -\boldsymbol{e}_r\mathrm{d}\theta, \mathrm{d}\boldsymbol{e}_r = \boldsymbol{e}_\theta\mathrm{d}\theta, \mathrm{d}\boldsymbol{e}_z = 0$$

Differential operators are given by [45]

$$\boldsymbol{\nabla} = \boldsymbol{e}_r\frac{\partial}{\partial r} + \frac{\boldsymbol{e}_\theta}{r}\frac{\partial}{\partial\theta} + \boldsymbol{e}_z\frac{\partial}{\partial z},$$

$$\boldsymbol{\nabla}\varphi = \boldsymbol{e}_r\frac{\partial\varphi}{\partial r} + \frac{\boldsymbol{e}_\theta}{r}\frac{\partial\varphi}{\partial\theta} + \boldsymbol{e}_z\frac{\partial\varphi}{\partial z}$$

$$\boldsymbol{\nabla}^2\varphi = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\varphi}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2\varphi}{\partial\theta^2} + \frac{\partial^2\varphi}{\partial z^2}$$

$$= \frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} + \frac{1}{r^2}\frac{\partial^2\varphi}{\partial\theta^2} + \frac{\partial^2\varphi}{\partial z^2}$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{v} = \frac{1}{r}\frac{\partial}{\partial r}(r\,v_r) + \frac{1}{r}\frac{\partial v_\theta}{\partial\theta} + \frac{\partial v_z}{\partial z}$$

$$\boldsymbol{\nabla}\times\boldsymbol{v} = \boldsymbol{e}_r\left(\frac{1}{r}\frac{\partial v_z}{\partial\theta} - \frac{\partial v_\theta}{\partial z}\right) + \boldsymbol{e}_\theta\left(\frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r}\right)$$

$$+\boldsymbol{e}_z\left[\frac{1}{r}\frac{\partial}{\partial r}(r\,v_\theta) - \frac{1}{r}\frac{\partial v_r}{\partial\theta}\right]$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{\tau} = \boldsymbol{e}_r\left[\frac{1}{r}\frac{\partial}{\partial r}(r\tau_{rr}) + \frac{1}{r}\frac{\partial\tau_{\theta r}}{\partial\theta} + \frac{\partial\tau_{zr}}{\partial z} - \frac{\tau_{\theta\theta}}{r}\right] +$$

$$+\boldsymbol{e}_\theta\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\tau_{r\theta}\right) + \frac{1}{r}\frac{\partial\tau_{\theta\theta}}{\partial\theta} + \frac{\partial\tau_{z\theta}}{\partial z} + \frac{\tau_{\theta r}-\tau_{r\theta}}{r}\right] +$$

$$+\boldsymbol{e}_z\left[\frac{1}{r}\frac{\partial}{\partial r}(r\tau_{rz}) + \frac{1}{r}\frac{\partial\tau_{\theta z}}{\partial\theta} + \frac{\partial\tau_{zz}}{\partial z}\right]$$

$$\boldsymbol{\nabla}\boldsymbol{v} = \boldsymbol{e}_r\boldsymbol{e}_r\frac{\partial v_r}{\partial r} + \boldsymbol{e}_r\boldsymbol{e}_\theta\frac{\partial v_\theta}{\partial r} + \boldsymbol{e}_r\boldsymbol{e}_z\frac{\partial v_z}{\partial r} +$$

$$+\boldsymbol{e}_\theta\boldsymbol{e}_r\left(\frac{1}{r}\frac{\partial v_r}{\partial\theta} - \frac{v_\theta}{r}\right) + \boldsymbol{e}_\theta\boldsymbol{e}_\theta\left(\frac{1}{r}\frac{\partial v_\theta}{\partial\theta} + \frac{v_r}{r}\right) +$$

$$+\boldsymbol{e}_\theta\boldsymbol{e}_z\frac{1}{r}\frac{\partial v_z}{\partial\theta} + \boldsymbol{e}_z\boldsymbol{e}_r\frac{\partial v_r}{\partial z} + \boldsymbol{e}_z\boldsymbol{e}_\theta\frac{\partial v_\theta}{\partial z} + \boldsymbol{e}_z\boldsymbol{e}_z\frac{\partial v_z}{\partial z}$$

$$\nabla^2\boldsymbol{v} = \boldsymbol{e}_r\left[\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial}{\partial r}(r\,v_r)\right) + \frac{1}{r^2}\frac{\partial^2 v_r}{\partial\theta^2} + \frac{\partial^2 v_r}{\partial z^2}\right.$$

$$\left.-\frac{2}{r^2}\frac{\partial v_\theta}{\partial\theta}\right] +$$

$$+\boldsymbol{e}_\theta\left[\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial}{\partial r}(r\,v_\theta)\right) + \frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial\theta^2} + \frac{\partial^2 v_\theta}{\partial z^2} + \frac{2}{r^2}\frac{\partial v_r}{\partial\theta}\right] +$$

$$+\boldsymbol{e}_z\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 v_z}{\partial\theta^2} + \frac{\partial^2 v_z}{\partial z^2}\right]$$

For *spherical coordinates*, the geometry is shown in Figure 17. The coordinates are related to cartesian coordinates by

Figure 17. Spherical coordinate system

$x = r\sin\theta\cos\varphi \qquad r = \sqrt{x^2+y^2+z^2}$

$y = r\sin\theta\sin\varphi \qquad \theta = \arctan\left(\sqrt{x^2+y^2}/z\right)$

$z = r\cos\theta \qquad \varphi = \arctan\left(\frac{y}{x}\right)$

The unit vectors are related by

$$\boldsymbol{e}_r = \sin\theta\cos\varphi\boldsymbol{e}_x + \sin\theta\sin\varphi\boldsymbol{e}_y + \cos\theta\boldsymbol{e}_z$$
$$\boldsymbol{e}_\theta = \cos\theta\cos\varphi\boldsymbol{e}_x + \cos\theta\sin\varphi\boldsymbol{e}_y - \sin\theta\boldsymbol{e}_z$$
$$\boldsymbol{e}_\phi = -\sin\varphi\boldsymbol{e}_x + \cos\varphi\boldsymbol{e}_y$$
$$\boldsymbol{e}_x = \sin\theta\cos\varphi\boldsymbol{e}_r + \cos\theta\cos\varphi\boldsymbol{e}_\theta - \sin\varphi\boldsymbol{e}_\phi$$
$$\boldsymbol{e}_y = \sin\theta\sin\varphi\boldsymbol{e}_r + \cos\theta\sin\varphi\boldsymbol{e}_\theta + \cos\varphi\boldsymbol{e}_\phi$$
$$\boldsymbol{e}_z = \cos\theta\boldsymbol{e}_r - \sin\theta\boldsymbol{e}_\theta$$

Derivatives of the unit vectors are

$$\frac{\partial\boldsymbol{e}_r}{\partial\theta} = \boldsymbol{e}_\theta,\ \frac{\partial\boldsymbol{e}_\theta}{\partial\theta} = -\boldsymbol{e}_r$$
$$\frac{\partial\boldsymbol{e}_r}{\partial\varphi} = e_\phi\sin\theta,\ \frac{\partial\boldsymbol{e}_\theta}{\partial\varphi} = \boldsymbol{e}_\phi\cos\theta,$$
$$\frac{\partial\boldsymbol{e}_\phi}{\partial\varphi} = -\boldsymbol{e}_r\sin\theta - \boldsymbol{e}_\theta\cos\theta$$

Others 0

Differential operators are given by [45]

$$\boldsymbol{\nabla} = \boldsymbol{e}_r\frac{\partial}{\partial r} + \boldsymbol{e}_\theta\frac{1}{r}\frac{\partial}{\partial\theta} + \boldsymbol{e}_\phi\frac{1}{r\sin\theta}\frac{\partial}{\partial\varphi},$$

$$\boldsymbol{\nabla}\psi = \boldsymbol{e}_r\frac{\partial\psi}{\partial r} + \boldsymbol{e}_\theta\frac{1}{r}\frac{\partial\psi}{\partial\theta} + \boldsymbol{e}_\phi\frac{1}{r\sin\theta}\frac{\partial\psi}{\partial\varphi}$$

$$\boldsymbol{\nabla}^2\psi = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial\psi}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right) + $$
$$+\frac{1}{r^2\sin^2\theta}\frac{\partial^2\psi}{\partial\varphi^2}$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{v} = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 v_r\right) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(v_\theta\sin\theta\right) + $$
$$+\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\varphi}$$

$$\boldsymbol{\nabla}\times\boldsymbol{v} = \boldsymbol{e}_r\left[\frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(v_\phi\sin\theta\right) - \frac{1}{r\sin\theta}\frac{\partial v_\theta}{\partial\varphi}\right] + $$
$$+\boldsymbol{e}_\theta\left[\frac{1}{r\sin\theta}\frac{\partial v_r}{\partial\varphi} - \frac{1}{r}\frac{\partial}{\partial r}\left(r\,v_\phi\right)\right] + $$
$$+\boldsymbol{e}_\phi\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\,v_\theta\right) - \frac{1}{r}\frac{\partial v_r}{\partial\theta}\right]$$

$$\boldsymbol{\nabla}\cdot\boldsymbol{\tau} = \boldsymbol{e}_r\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\tau_{rr}\right)\right.$$
$$\left.+\frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(\tau_{\theta r}\sin\theta\right) + \frac{1}{r\sin\theta}\frac{\partial\tau_{\phi r}}{\partial\varphi} - \frac{\tau_{\theta\theta}+\tau_{\phi\phi}}{r}\right] + $$
$$+\boldsymbol{e}_\theta\left[\frac{1}{r^3}\frac{\partial}{\partial r}\left(r^3\tau_{r\theta}\right) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(\tau_{\theta\theta}\sin\theta\right) + \right.$$
$$\left.\frac{1}{r\sin\theta}\frac{\partial\tau_{\phi\theta}}{\partial\varphi} + \frac{\tau_{\theta r}-\tau_{r\theta}-\tau_{\phi\phi}\cot\theta}{r}\right] + $$
$$+\boldsymbol{e}_\phi\left[\frac{1}{r^3}\frac{\partial}{\partial r}\left(r^3\tau_{r\phi}\right) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(\tau_{\theta\phi}\sin\theta\right) + \right.$$
$$\left.\frac{1}{r\sin\theta}\frac{\partial\tau_{\phi\phi}}{\partial\varphi} + \frac{\tau_{\phi r}-\tau_{r\phi}+\tau_{\phi\theta}\cot\theta}{r}\right]$$

$$\boldsymbol{\nabla}\boldsymbol{v} = \boldsymbol{e}_r\boldsymbol{e}_r\frac{\partial v_r}{\partial r} + \boldsymbol{e}_r\boldsymbol{e}_\theta\frac{\partial v_\theta}{\partial r} + \boldsymbol{e}_r\boldsymbol{e}_\phi\frac{\partial v_\phi}{\partial r} + $$
$$+\boldsymbol{e}_\theta\boldsymbol{e}_r\left(\frac{1}{r}\frac{\partial v_r}{\partial\theta} - \frac{v_\theta}{r}\right) + \boldsymbol{e}_\theta\boldsymbol{e}_\theta\left(\frac{1}{r}\frac{\partial v_\theta}{\partial\theta} + \frac{v_r}{r}\right) + $$
$$+\boldsymbol{e}_\theta\boldsymbol{e}_\phi\frac{1}{r}\frac{\partial v_\phi}{\partial\theta} + \boldsymbol{e}_\phi\boldsymbol{e}_r\left(\frac{1}{r\sin\theta}\frac{\partial v_r}{\partial\varphi} - \frac{v_\phi}{r}\right) + $$
$$+\boldsymbol{e}_\phi\boldsymbol{e}_\theta\left(\frac{1}{r\sin\theta}\frac{\partial v_\theta}{\partial\varphi} - \frac{v_\phi}{r}\cot\theta\right) + $$
$$+\boldsymbol{e}_\phi\boldsymbol{e}_\phi\left(\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\varphi} + \frac{v_r}{r} + \frac{v_\theta}{r}\cot\theta\right)$$

$$\nabla^2\boldsymbol{v} = \boldsymbol{e}_r\left[\frac{\partial}{\partial r}\left(\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\,v_r\right)\right)\right.$$
$$+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial v_r}{\partial\theta}\right)$$
$$\left.+\frac{1}{r^2\sin^2\theta}\frac{\partial^2 v_r}{\partial\varphi^2} - \frac{2}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(v_\theta\sin\theta\right) - \frac{2}{r^2\sin\theta}\frac{\partial v_\phi}{\partial\varphi}\right]$$
$$+\boldsymbol{e}_\theta\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial v_\theta}{\partial r}\right) + \frac{1}{r^2}\frac{\partial}{\partial\theta}\left(\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(v_\theta\sin\theta\right)\right)\right.$$
$$\left.+\frac{1}{r^2\sin^2\theta}\frac{\partial^2 v_\theta}{\partial\varphi^2} + \frac{2}{r^2}\frac{\partial v_r}{\partial\theta} - \frac{2}{r^2}\frac{\cot\theta}{\sin\theta}\frac{\partial v_\phi}{\partial\varphi}\right]$$
$$+\boldsymbol{e}_\phi\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial v_\phi}{\partial r}\right) + \frac{1}{r^2}\frac{\partial}{\partial\theta}\left(\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(v_\phi\sin\theta\right)\right)\right.$$
$$\left.+\frac{1}{r^2\sin^2\theta}\frac{\partial^2 v_\phi}{\partial\varphi^2} + \frac{2}{r^2\sin\theta}\frac{\partial v_r}{\partial\varphi} + \frac{2}{r^2}\frac{\cot\theta}{\sin\theta}\frac{\partial v_\theta}{\partial\varphi}\right]$$

6. Ordinary Differential Equations as Initial Value Problems

A differential equation for a function that depends on only one variable (often time) is called an ordinary differential equation. The general solution to the differential equation includes many possibilities; the boundary or initial conditions are required to specify which of those are desired. If all conditions are at one point, the problem is an initial value problem and can be integrated from that point on. If some of the conditions are available at one point and others at another point, the ordinary differential equations become two-point boundary value problems, which are treated in Chapter 7. Initial value problems as ordinary differential equations arise in control of lumped-parameter models, transient models of stirred tank reactors, polymerization reactions and plug-flow reactors, and generally in models where no spatial gradients occur in the unknowns.

6.1. Solution by Quadrature

When only one equation exists, even if it is nonlinear, solving it by quadrature may be possible. For

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f\ (y)$$

$$y\ (0) = y_0$$

the problem can be separated

$$\frac{\mathrm{d}y}{f\ (y)} = \mathrm{d}t$$

and integrated:

$$\int_{y_0}^{y} \frac{\mathrm{d}y'}{f\ (y')} = \int_0^t \mathrm{d}t = t$$

If the quadrature can be performed analytically then the exact solution has been found.

For example, consider the kinetics problem with a second-order reaction.

$$\frac{\mathrm{d}c}{\mathrm{d}t} = -kc^2, c\ (0) = c_0$$

To find the function of the concentration versus time, the variables can be separated and integrated.

$$\frac{\mathrm{d}c}{c^2} = -k\mathrm{d}t,$$

$$-\frac{1}{c} = -kt+D$$

Application of the initial conditions gives the solution:

$$\frac{1}{c} = kt+\frac{1}{c_0}$$

For other ordinary differential equations an integrating factor is useful. Consider the problem governing a stirred tank with entering fluid having concentration c_{in} and flow rate F, as shown in Figure 18. The flow rate out is also F and the volume of the tank is V. If the tank is completely mixed, the concentration in the tank is c and the concentration of the fluid leaving the tank is also c. The differential equation is then

$$V\frac{\mathrm{d}c}{\mathrm{d}t} = F\ (c_{\mathrm{in}}-c)\ ,\ c\ (0) = c_0$$

Upon rearrangement,

$$\frac{\mathrm{d}c}{\mathrm{d}t}+\frac{F}{V}c = \frac{F}{V}c_{\mathrm{in}}$$

is obtained. An integrating factor is used to solve this equation. The integrating factor is a function that can be used to turn the left-hand side into an exact differential and can be found by using Fréchet differentials [51]. In this case,

$$\exp\left(\frac{F\,t}{V}\right)\left[\frac{\mathrm{d}c}{\mathrm{d}t}+\frac{F}{V}c\right] = \frac{\mathrm{d}}{\mathrm{d}t}\left[\exp\left(\frac{F\,t}{V}\right)c\right]$$

Thus, the differential equation can be written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\exp\left(\frac{F\,t}{V}\right)c\right] = \exp\left(\frac{F\,t}{V}\right)\left[\frac{F}{V}c_{\mathrm{in}}\right]$$

This can be integrated once to give

$$\exp\left(\frac{F\,t}{V}\right)c = c\ (0)+\frac{F}{V}\int_0^t \exp\left(\frac{F\,t'}{V}\right)c_{\mathrm{in}}\ (t')\ \mathrm{d}t'$$

or

$$c\ (t) = \exp\left(-\frac{F\,t}{V}\right)c_0$$

$$+\frac{F}{V}\int_0^t \exp\left(-\frac{F\,(t-t')}{V}\right)c_{\mathrm{in}}\ (t')\,\mathrm{d}t'$$

If the integral on the right-hand side can be calculated, the solution can be obtained analytically. If not, the numerical methods described in the next sections can be used. Laplace transforms can also be attempted. However, an analytic solution is so useful that quadrature and an integrating factor should be tried before resorting to numerical solution.

Figure 18. Stirred tank

6.2. Explicit Methods

Consider the ordinary differential equation

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f\ (y)$$

Multiple equations that are still initial value problems can be handled by using the same techniques discussed here. A higher order differential equation

$$y^{(n)}+F\left(y^{(n-1)}, y^{(n-2)},\ldots, y', y\right) = 0$$

with initial conditions

$$G_i\ \left(y^{(n-1)}\,(0)\,, y^{(n-2)}\ (0)\,,\ldots,y'\ (0)\,, y\ (0)\right) = 0$$

$$i = 1,\ldots,n$$

can be converted into a set of first-order equations. By using

$$y_i \equiv y^{(i-1)} = \frac{\mathrm{d}^{(i-1)}\,y}{\mathrm{d}t^{(i-1)}} = \frac{\mathrm{d}}{\mathrm{d}t}\,y^{(i-2)} = \frac{\mathrm{d}y_{i-1}}{\mathrm{d}t}$$

the higher order equation can be written as a set of first-order equations:

$$\frac{\mathrm{d}y_1}{\mathrm{d}t} = y_2$$

$$\frac{\mathrm{d}y_2}{\mathrm{d}t} = y_3$$

$$\frac{\mathrm{d}y_3}{\mathrm{d}t} = y_4$$

$$\ldots$$

$$\frac{\mathrm{d}y_n}{\mathrm{d}t} = -\,F\,(y_{n-1}, y_{n-2},\ldots,y_2,\, y_1)$$

The initial conditions would have to be specified for variables $y_1(0), \ldots, y_n\ (0)$, or equivalently $y\ (0), \ldots, y^{(n-1)}\ (0)$. The set of equations is then written as

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \boldsymbol{f}\,(\boldsymbol{y}, t)$$

All the methods in this chapter are described for a single equation; the methods apply to the multiple equations as well. Taking the single equation in the form

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f\ (y)$$

multiplying by dt, and integrating once yields

$$\int_{t_n}^{t_{n+1}} \frac{\mathrm{d}y}{\mathrm{d}t'}\,\mathrm{d}t' = \sum_{t_n}^{t_{n+1}} f\ \left(y\ (t')\right)\mathrm{d}t'$$

This is

$$y^{n+1} = y^n + \int_{t_n}^{t_{n+1}} \frac{\mathrm{d}y}{\mathrm{d}t'}\,\mathrm{d}t'$$

The last substitution gives a basis for the various methods. Different interpolation schemes for $y\ (t)$ provide different integration schemes; using low-order interpolation gives low-order integration schemes [3].

Euler's method is first order

$$y^{n+1} = y^n + \Delta t f\,(y^n)$$

Adams – Bashforth Methods. The *second-order* Adams – Bashforth method is

$$y^{n+1} = y^n + \frac{\Delta\,t}{2}\left[3\,f\ (y^n)\ - f\ \left(y^{n-1}\right)\right]$$

The *fourth-order* Adams – Bashforth method is

$$y^{n+1} = y^n + \frac{\Delta\,t}{24}\left[55\,f\ (y^n)\ - 59\,f\ \left(y^{n-1}\right)\right.$$
$$\left. +37\,f\ \left(y^{n\,-\,2}\right)\ - 9\,f\ \left(y^{n-3}\right)\right]$$

Notice that the higher order explicit methods require knowing the solution (or the right-hand side) evaluated at times in the past. Because these were calculated to get to the current time, this presents no problem except for starting the evaluation. Then, Euler's method may have to be used with a very small step size for several steps to generate starting values at a succession of time points. The error terms, order of the method, function evaluations per step, and stability limitations are listed in Table 6. The advantage of the fourth-order Adams – Bashforth method is that it uses only one function evaluation per step and yet achieves high-order accuracy. The disadvantage is the necessity of using another method to start.

Runge – Kutta Methods. Runge – Kutta methods are explicit methods that use several function evaluations for each time step. The general form of the methods is

$$y^{n+1} = y^n + \sum_{i=1}^{v} w_i\,k_i$$

with

$$k_i = \Delta t\,f\left(t^n + c_i\Delta t, y^n + \sum_{j=1}^{i-1} a_{ij}\,k_j\right)$$

Runge – Kutta methods traditionally have been writen for $f\ (t,\ y)$ and that is done here, too. If these equations are expanded and compared with a Taylor series, restrictions can be placed on the parameters of the method to make it first order, second order, etc. Even so, additional parameters can be chosen. A *second-order* Runge – Kutta method is

$$y^{n+1} = y^n + \frac{\Delta t}{2}\left[f^n + f\ \left(t^n + \Delta t, y^n + \Delta t\,f^{\,n}\right)\right]$$

The midpoint scheme is another second-order Runge – Kutta method:

Table 6. Properties of integration methods for ordinary differential equations

Method	Error term	Order	Function evaluations per step	Stability limit, $\lambda\ \Delta t \leq$
Explicit methods				
Euler	$\frac{h^2}{2}y''$	1	1	2.0
Second-order Adams – Bashforth	$\frac{5}{12}h^3y'''$	2	1	
Fourth-order Adams – Bashforth	$\frac{251}{720}h^5y^{(5)}$	4	1	0.3
Second-order Runge – Kutta (midpoint)		2	2	2.0
Runge – Kutta – Gill		4	4	2.8
Runge – Kutta – Feldberg	$y^{n+1}-z^{n+1}$	5	6	3.0
Predictor – corrector methods				
Second-order Runge – Kutta		2	2	2.0
Adams, fourth-order		2	2	1.3
Implicit methods, stability limit ∞				
Backward Euler		1	many, iterative	∞ *
Trapezoid rule	$-\frac{1}{12}h^3y'''$	2	many, iterative	2 *
Fourth-order Adams – Moulton		4	many, iterative	3 *

* Oscillation limit, $\lambda\ \Delta t \leq$.

$$y^{n+1} = y^n + \Delta t\ f\ \left(t^n + \frac{\Delta t}{2}, y^n + \frac{\Delta t}{2}\ f^n\right)$$

A popular *fourth-order* method is the Runge – Kutta – Gill method with the formulas

$$k_1 = \Delta t\ f\ (t^n, y^n)$$

$$k_2 = \Delta t\ f\ \left(t^n + \tfrac{\Delta t}{2}, y^n + \tfrac{k_1}{2}\right)$$

$$k_3 = \Delta t\ f\ \left(t^n + \tfrac{\Delta t}{2}, y^n + a\,k_1 + b\,k_2\right)$$

$$k_4 = \Delta t\ f\ (t^n + \Delta t, y^n + c\,k_2 + d\,k_3)$$

$$y^{n+1} = y^n + \tfrac{1}{6}\,(k_1 + k_4) + \tfrac{1}{3}\,(b\,k_2 + d\,k_3)$$

$$a = \tfrac{\sqrt{2}-1}{2}, b = \tfrac{2-\sqrt{2}}{2},$$

$$c = -\tfrac{\sqrt{2}}{2}, d = 1 + \tfrac{\sqrt{2}}{2}$$

Another fourth-order Runge – Kutta method is given by the Runge – Kutta – Feldberg formulas [52]; although the method is fourth-order, it achieves fifth-order accuracy. The popular integration package RKF 45 is based on this method.

$$k_1 = \Delta t\ f\ (t^n, y^n)$$

$$k_2 = \Delta t\ f\ \left(t^n + \tfrac{\Delta t}{4}, y^n + \tfrac{k_1}{4}\right)$$

$$k_3 = \Delta t\ f\ \left(t^n + \tfrac{3}{8}\Delta t, y^n + \tfrac{3}{32}k_1 + \tfrac{9}{32}k_2\right)$$

$$k_4 = \Delta t f\ \left(t^n + \tfrac{12}{13}\Delta t, y^n + \tfrac{1932}{2197}k_1 - \tfrac{7200}{2197}k_2 + \tfrac{7296}{2197}k_3\right)$$

$$k_5 = \Delta t f\ \left(t^n + \Delta t, y^n + \tfrac{439}{216}k_1 - 8\,k_2 + \tfrac{3680}{513}k_3 - \tfrac{845}{4104}k_4\right)$$

$$k_6 = \Delta t\ f\ \left(t^n + \tfrac{\Delta t}{2}, y^n - \tfrac{8}{27}k_1 + 2k_2 - \tfrac{3544}{2565}k_3 + \tfrac{1859}{4104}k_4 - \tfrac{11}{40}k_5\right)$$

$$y^{n+1} = y^n + \tfrac{25}{216}k_1 + \tfrac{1408}{2565}k_3 + \tfrac{2197}{4104}k_4 - \tfrac{1}{5}k_5$$

$$z^{n+1} = y^n + \tfrac{16}{135}k_1 + \tfrac{6656}{12\,825}k_3 + \tfrac{28\,561}{56\,430}k_4 - \tfrac{9}{50}k_5 + \tfrac{2}{55}k_6$$

The value of $y^{n+1} - z^{n+1}$ is an estimate of the error in y^{n+1} and can be used in step-size control schemes.

Generally, a high-order method should be used to achieve high accuracy. The Runge – Kutta – Gill method is popular because it is high order and does not require a starting method (as does the fourth-order Adams – Bashforth method). However, it requires four function evaluations per time step, or four times as many as the Adams – Bashforth method. For problems in which the function evaluations are a significant portion of the calculation time this might be important. Given the speed of computers and the widespread availability of desktop computers, the efficiency of a method is most important only for very large problems that are going to be solved many times. For other problems the most important criterion for choosing a method is probably the time the user spends setting up the problem.

The stability of an integration method is best estimated by determining the rational polynomial corresponding to the method. Apply this method to the equation

$$\frac{\mathrm{d}y}{\mathrm{d}t} = -\lambda y, y(0) = 1$$

and determine the formula for r_{mn}:

$$y^{k+1} = r_{mn}(\lambda \Delta t) y^k$$

The rational polynomial is defined as

$$r_{mn}(z) = \frac{p_n(z)}{q_m(z)} \approx e^{-z}$$

and is an approximation to exp $(-z)$, called a Padé approximation. The stability limits are the largest positive z for which

$$|r_{mn}(z)| \leq 1$$

The method is A acceptable if the inequality holds for $Re\, z > 0$. It is $A(0)$ acceptable if the inequality holds for z real, $z > 0$ [53]. The method will not induce oscillations about the true solution provided

$$r_{mn}(z) > 0$$

A method is L acceptable if it is A acceptable and

$$\lim_{z \to \infty} r_{mn}(z) = 0$$

For example, Euler's method gives

$$y^{n+1} = y^n - \lambda \Delta t y^n \text{ or } y^{n+1} = (1 - \lambda \Delta t) y^n$$

$$\text{or } r_{mn} = 1 - \lambda \Delta t$$

The stability limit is then

$$\lambda \Delta t \leq 2$$

The Euler method will not oscillate provided

$$\lambda \Delta t \leq 1$$

The stability limits listed in Table 6 are obtained in this fashion. The limit for the Euler method is 2.0; for the Runge – Kutta – Gill method it is 2.785; for the Runge – Kutta – Feldberg method it is 3.020. The rational polynomials for the various explicit methods are illustrated in Figure 19. As can be seen, the methods approximate the exact solution well as $\lambda \Delta t$ approaches zero, and the higher order methods give a better approximation at high values of $\lambda \Delta t$.

Figure 19. Rational approximations for explicit methods a) Euler; b) Runge – Kutta – 2; c) Runge – Kutta – Gill; d) Exact curve; e) Runge – Kutta – Feldberg

In solving sets of equations

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \boldsymbol{A}\boldsymbol{y} + \boldsymbol{f}, \boldsymbol{y}(0) = y_0$$

all the eigenvalues of the matrix $\boldsymbol{A}$ must be examined. Finlayson [3] and Amundson [54, p. 197 – 199] both show how to transform these equations into an orthogonal form so that each equation becomes one equation in one unknown, for which single equation analysis applies. For linear problems the eigenvalues do not change, so the stability and oscillation limits must be satisfied for every eigenvalue of the matrix $\boldsymbol{A}$. When solving nonlinear problems the equations are linearized about the solution at the local time, and the analysis applies for small changes in time, after which a new analysis about the new solution must be made. Thus, for nonlinear problems the eigenvalues keep changing.

Richardson extrapolation can be used to improve the accuracy of a method. Step forward one step Δt with a p-th order method. Then redo the problem, this time stepping forward from the same initial point but in two steps of length $\Delta t/2$, thus ending at the same point. Call the solution of the one-step calculation y_1 and the solution of the two-step calculation y_2. Then an improved solution at the new time is given by

$$y = \frac{2^p y_2 - y_1}{2^p - 1}$$

This gives a good estimate provided Δt is small enough that the method is truly convergent with

order p. This process can also be repeated in the same way Romberg's method was used for quadrature (see Section 2.4).

The accuracy of a numerical calculation depends on the step size used, and this is chosen automatically by efficient codes. For example, in the Euler method the local truncation error LTE is

$$\text{LTE} = \frac{\Delta t^2}{2} y_n''$$

Yet the second derivative can be evaluated by using the difference formulas as

$$y_n'' = \nabla(\Delta t\, y_n') = \Delta t\, (y_n' - y_{n-1}') =$$

$$\Delta t\, (f_n - f_{n-1})$$

Thus, by monitoring the difference between the right-hand side from one time step to another, an estimate of the truncation error is obtained. This error can be reduced by reducing Δt. If the user specifies a criterion for the largest local error estimate, then Δt is reduced to meet that criterion. Also, Δt is increased to as large a value as possible, because this shortens computation time. If the local truncation error has been achieved (and estimated) by using a step size Δt_1

$$\text{LTE} = c\, \Delta t_1^p$$

and the desired error is ε, to be achieved using a step size Δt_2

$$\varepsilon = c\, \Delta t_2^p$$

then the next step size Δt_2 is taken from

$$\frac{\text{LTE}}{\varepsilon} = \left(\frac{\Delta t_1}{\Delta t_2}\right)^p$$

Generally, things should not be changed too often or too drastically. Thus one may choose not to increase Δt by more than a factor (such as 2) or to increase Δt more than once every so many steps (such as 5) [55]. In the most sophisticated codes the alternative exists to change the order of the method as well. In this case, the truncation error of the orders one higher and one lower than the current one are estimated, and a choice is made depending on the expected step size and work.

6.3. Implicit Methods

By using different interpolation formulas, involving y^{n+1}, implicit integration methods can be derived. Implicit methods result in a nonlinear equation to be solved for y^{n+1} so that iterative methods must be used. The backward Euler method is a first-order method:

$$y^{n+1} = y^n + \Delta t\, f\, (y^{n+1})$$

The trapezoid rule (see Section 2.4) is a second-order method:

$$y^{n+1} = y^n + \frac{\Delta t}{2} \left[f\, (y^n) + f\, (y^{n+1}) \right]$$

When the trapezoid rule is used with the finite difference method for solving partial differential equations it is called the Crank – Nicolson method. Adams methods exist as well, and the fourth-order Adams – Moulton method is

$$y^{n+1} = y^n + \frac{\Delta t}{24} \left[9 f\, (y^{n+1}) + 19 f\, (y^n) - 5 f\, (y^{n-1}) + f\, (y^{n-2}) \right]$$

The properties of these methods are given in Table 6. The implicit methods are stable for any step size but do require the solution of a set of nonlinear equations, which must be solved iteratively. An application to dynamic distillation problems is given in [56].

All these methods can be written in the form

$$y^{n+1} = \sum_{i=1}^{k} \alpha_i\, y^{n+1-i} + \Delta t \sum_{i=0}^{k} \beta_i\, f\, (y^{n+1-i})$$

or

$$y^{n+1} = \Delta t\, \beta_0\, f\, (y^{n+1}) + w^n$$

where w^n represents known information. This equation (or set of equations for more than one differential equation) can be solved by using successive substitution:

$$y^{n+1,\, k+1} = \Delta t\, \beta_0 f \left(y^{n+1,\, k} \right) + w^n$$

Here, the superscript k refers to an iteration counter. The successive substitution method is guaranteed to converge, provided the first derivative of the function is bounded and a small enough time step is chosen. Thus, if it has not converged within a few iterations, Δt can be reduced and the iterations begun again. The *Newton – Raphson method* (see Section 1.2) can also be used.

In many computer codes, iteration is allowed to proceed only a fixed number of times (e.g.,

three) before Δt is reduced. Because a good history of the function is available from previous time steps, a good initial guess is usually possible.

The best software packages for stiff equations (see Section 6.4) use Gear's backward difference formulas. The formulas of various orders are [57].

$$1: y^{n+1} = y^n + \Delta t\, f\left(y^{n+1}\right)$$

$$2: y^{n+1} = \tfrac{4}{3}\, y^n - \tfrac{1}{3}\, y^{n-1} + \tfrac{2}{3}\, \Delta t\, f\left(y^{n+1}\right)$$

$$3: y^{n+1} = \tfrac{18}{11}\, y^n - \tfrac{9}{11}\, y^{n-1} + \tfrac{2}{11}\, y^{n-2} + \tfrac{6}{11}\, \Delta t\, f\left(y^{n+1}\right)$$

$$4: y^{n+1} = \tfrac{48}{25}\, y^n - \tfrac{36}{25}\, y^{n-1} + \tfrac{16}{25}\, y^{n-2} - \tfrac{3}{25}\, y^{n-3} + \tfrac{12}{25}\, \Delta t\, f\left(y^{n+1}\right)$$

$$5: y^{n+1} = \tfrac{300}{137}\, y^n - \tfrac{300}{137}\, y^{n-1} + \tfrac{200}{137}\, y^{n-2} - \tfrac{75}{137}\, y^{n-3} + \tfrac{12}{137}\, y^{n-4} + \tfrac{60}{137}\, \Delta t\, f\left(y^{n+1}\right)$$

The stability properties of these methods are determined in the same way as explicit methods. They are always expected to be stable, no matter what the value of Δt is, and this is confirmed in Figure 20.

Figure 20. Rational approximations for implicit methods a) Backward Euler; b) Exact curve; c) Trapezoid; d) Euler

Predictor – corrector methods can be employed in which an explicit method is used to predict the value of y^{n+1}. This value is then used in an implicit method to evaluate $f\,(\,y^{n+1})$.

6.4. Stiffness

Why is it desirable to use implicit methods that lead to sets of algebraic equations that must be solved iteratively whereas explicit methods lead to a direct calculation? The reason lies in the stability limits; to understand their impact, the concept of stiffness is necessary. When modeling a physical situation, the time constants governing different phenomena should be examined. Consider flow through a packed bed, as illustrated in Figure 21.

Figure 21. Flow through packed bed

The superficial velocity u is given by

$$u = \frac{Q}{A\,\varphi}$$

where Q is the volumetric flow rate, A is the cross-sectional area, and φ is the void fraction. A time constant for flow through the device is then

$$t_{\text{flow}} = \frac{L}{u} = \frac{\varphi\, A\, L}{Q}$$

where L is the length of the packed bed. If a chemical reaction occurs, with a reaction rate given by

$$\frac{\text{Moles}}{\text{Volume time}} = -k\,c$$

where k is the rate constant (time^{-1}) and c is the concentration (moles/volume), the characteristic time for the reaction is

$$t_{\text{rxn}} = \frac{1}{k}$$

If diffusion occurs inside the catalyst, the time constant is

$$t_{\text{internal diffusion}} = \frac{\varepsilon\, R^2}{D_{\text{e}}}$$

where ε is the porosity of the catalyst, R is the catalyst radius, and D_{e} is the effective diffusion

coefficient inside the catalyst. The time constant for heat transfer is

$$t_{\text{internal heat transfer}} = \frac{R^2}{\alpha} = \frac{\varrho_{\mathrm{s}} C_{\mathrm{s}} R^2}{k_{\mathrm{e}}}$$

where ϱ_{s} is the catalyst density, C_{s} is the catalyst heat capacity per unit mass, k_{e} is the effective thermal conductivity of the catalyst, and α is the thermal diffusivity. The time constants for diffusion of mass and heat through a boundary layer surrounding the catalyst are

$$t_{\text{external diffusion}} = \frac{R}{k_{\mathrm{g}}}$$

$$t_{\text{external heat transfer}} = \frac{\varrho_{\mathrm{s}} C_{\mathrm{s}} R}{h_{\mathrm{p}}}$$

where k_{g} and h_{p} are the mass-transfer and heat-transfer coefficients, respectively. The importance of examining these time constants comes from realization that their orders of magnitude differ greatly. For example, in the model of an automobile catalytic converter [58] the time constant for internal diffusion was 0.3 s, for internal heat transfer 21 s, and for flow through the device 0.003 s. Flow through the device is so fast that it might as well be instantaneous. Thus, the time derivatives could be dropped from the mass balance equations for the flow, leading to a set of differential-algebraic equations (see below). If the original equations had to be solved, the eigenvalues would be roughly proportional to the inverse of the time constants. The time interval over which to integrate would be a small number (e.g., five) multiplied by the longest time constant. Yet the explicit stability limitation applies to all the eigenvalues, and the largest eigenvalue would determine the largest permissible time step. Here, $\lambda = 1/0.003\ \mathrm{s}^{-1}$. Very small time steps would have to be used, e.g., $\Delta t \leq 2 \times 0.003$ s, but a long integration would be required to reach steady state. Such problems are termed stiff, and implicit methods are very useful for them. In that case the stable time constant is not of any interest, because any time step is stable. What is of interest is the largest step for which a solution can be found. If a time step larger than the smallest time constant is used, then any phenomena represented by that smallest time constant will be overlooked—at least transients in it will be smeared over. However, the method will still be stable. Thus, if the very rapid transients of part of the model are not of interest, they can be ignored and an implicit method used [59].

The idea of stiffness is best explained by considering a system of linear equations:

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \boldsymbol{A}\,\boldsymbol{y}$$

Let λ_i be the eigenvalues of the matrix $\boldsymbol{A}$. This system can be converted into a system of n equations, each of them having only one unknown; the eigenvalues of the new system are the same as the eigenvalues of the original system [3, pp. 39 – 42], [54, pp. 197 – 199]. Then the stiffness ratio SR is defined as [53, p. 32]

$$\mathrm{SR} = \frac{\max_i |\mathrm{Re}\,(\lambda_i)|}{\min_i |\mathrm{Re}\,(\lambda_i)|}$$

SR = 20 is not stiff, SR = 10^3 is stiff, and SR = 10^6 is very stiff. If the problem is nonlinear, the solution is expanded about the current state:

$$\frac{\mathrm{d}y_i}{\mathrm{d}t} = f_i\left[\boldsymbol{y}\left(t^n\right)\right] + \sum_{j=1}^{n} \frac{\partial f_i}{\partial y_j}\left[y_j - y_j\left(t^n\right)\right]$$

The question of stiffness then depends on the eigenvalue of the Jacobian at the current time. Consequently, for nonlinear problems the problem can be stiff during one time period and not stiff during another. Packages have been developed for problems such as these. Although the chemical engineer may not actually calculate the eigenvalues, knowing that they determine the stability and accuracy of the numerical scheme, as well as the step size employed, is useful.

6.5. Differential – Algebraic Systems

Sometimes models involve ordinary differential equations subject to some algebraic constraints. For example, the equations governing one equilibrium stage (as in a distillation column) are

$$M\frac{\mathrm{d}x^n}{\mathrm{d}t} = V^{n+1}\,y^{n+1} - L^n\,x^n - V^n\,y^n + L^{n-1}\,x^{n-1}$$

$$x^{n-1} - x^n = E^n\left(x^{n-1} - x^{*,n}\right)$$

$$\sum_{i=1}^{N} x_i = 1$$

where x and y are the mole fractions in the liquid and vapor, respectively; L and V are liquid and vapor flow rates, respectively; M is the holdup; and the superscript n is the stage number. The efficiency is E, and the concentration in equilibrium with the vapor is x^*. The first equation is

an ordinary differential equation for the mass of one component on the stage, whereas the third equation represents a constraint that the mass fractions add to one. As a second example, the following kinetics problem can be considered:

$$\frac{\mathrm{d}c_1}{\mathrm{d}t} = f\ (c_1, c_2)$$

$$\frac{\mathrm{d}c_2}{\mathrm{d}t} = k_1\, c_1 - k_2\, c_2^2$$

The first equation could be the equation for a stirred tank reactor, for example. Suppose both k_1 and k_2 are large. The problem is then stiff, but the second equation could be taken at equilibrium. If

$$c_1 \rightleftarrows 2c_2$$

The equilibrium condition is then

$$\frac{c_2^2}{c_1} = \frac{k_1}{k_2} \equiv K$$

Under these conditions the problem becomes

$$\frac{\mathrm{d}c_1}{\mathrm{d}t} = f\ (c_1, c_2)$$

$$0 = k_l c_1 - k_2 c_2^2$$

Thus, a differential-algebraic system of equations is obtained. In this case, the second equation can be solved and substituted into the first to obtain differential equations, but in the general case that is not possible.

Differential-algebraic equations can be written in the general notation

$$\boldsymbol{F}\left(t, \boldsymbol{y}, \frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t}\right) = 0$$

or the variables and equations may be separated according to whether they come primarily from differential [$y(t)$] or algebraic equations [$x(t)$]:

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \boldsymbol{f}\ (t, \boldsymbol{y}, \boldsymbol{x}), \boldsymbol{g}\ (t, \boldsymbol{y}, \boldsymbol{x}) = 0$$

Another form is not strictly a differential-algebraic set of equations, but the same principles apply; this form arises frequently when the Galerkin finite element is applied:

$$\boldsymbol{A}\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \boldsymbol{f}\ (\boldsymbol{y})$$

The computer program DASSL [60, 61] can solve such problems. They can also be solved by writing the differential equation as

$$\frac{d\boldsymbol{y}}{dt} = \boldsymbol{A}^{-1}\boldsymbol{f}\ (\boldsymbol{y})$$

When $\boldsymbol{A}$ is independent of $\boldsymbol{y}$, the inverse (from LU decompositions) need be computed only once.

In actuality, higher order backward-difference Gear methods are used in the computer program DASSL [60, 61].

Differential-algebraic systems are more complicated than differential systems because the solution may not always be defined. Pontelides et al. [62] introduced the term "index" to identify possible problems. The index is defined as the minimum number of times the equations must be differentiated with respect to time to convert the system to a set ofordinary differential equations. These higher derivatives may not exist, and the process places limits on which variables can be given initial values. Sometimes the initial values must be constrained by the algebraic equations [62]. For a differential-algebraic system modeling a distillation tower, the index depends on the specification of pressure for the column [62]. Several chemical engineering examples of differential-algebraic systems and a solution for one involving two-phase flow are given in [63].

6.6. Computer Software

Efficient software packages are widely available for solving ordinary differential equations as initial value problems. In each of the packages the user specifies the differential equation to be solved and a desired error criterion. The package then integrates in time and adjusts the step size to achieve the error criterion, within the limitations imposed by stability.

A popular explicit Runge – Kutta package is RKF 45. An estimate of the truncation error at each step is available. Then the step size can be reduced until this estimate is below the user-specified tolerance. The method is thus automatic, and the user is assured of the results. Note, however, that the tolerance is set on the local truncation error, namely, from one step to another, whereas the user is generally interested in the global trunction error, i.e., the error after several steps. The global error is generally made smaller by making the tolerance smaller, but the absolute accuracy is not the same as the tolerance. If the problem is stiff, then very small step sizes are used and the computation becomes

very lengthy. The RKF 45 code discovers this and returns control to the user with a message indicating the problem is too hard to solve with RKF 45.

A popular implicit package is LSODE, a version of Gear's method [57] written by Alan Hindmarsh at Lawrence Livermore Laboratory. In this package, the user specifies the differential equation to be solved and the tolerance desired. Now the method is implicit and, therefore, stable for any step size. The accuracy may not be acceptable, however, and sets of nonlinear equations must be solved. Thus, in practice, the step size is limited but not nearly so much as in the Runge – Kutta methods. In these packages both the step size and the order of the method are adjusted by the package itself. Suppose a k-th order method is being used. The truncation error is determined by the $(k + 1)$-th order derivative. This is estimated by using difference formulas and the values of the right-hand sides at previous times. An estimate is also made for the k-th and $(k + 2)$-th derivative. Then, the errors in a $(k - 1)$-th order method, a k-th order method, and a $(k + 1)$-th order method can be estimated. Furthermore, the step size required to satisfy the tolerance with each of these methods can be determined. Then the method and step size for the next step that achieves the biggest step can be chosen, with appropriate adjustments due to the different work required for each order. The package generally starts with a very small step size and a first-order method—the backward Euler method. Then it integrates along, adjusting the order up (and later down) depending on the error estimates. The user is thus assured that the local truncation error meets the tolerance. A further difficulty arises because the set of nonlinear equations must be solved. Usually a good guess of the solution is available, because the solution is evolving in time and past history can be extrapolated. Thus, the Newton – Raphson method will usually converge. The package protects itself, though, by only doing a few (i.e., three) iterations. If convergence is not reached within these iterations, the step size is reduced and the calculation is redone for that time step. The convergence theorem for the Newton – Raphson method (Chap. 1) indicates that the method will converge if the step size is small enough. Thus, the method is guaranteed to work. Further economies are possible. The Jacobian needed in the Newton – Raphson method can be fixed over several time steps. Then if the iteration does not converge, the Jacobian can be reevaluated at the current time step. If the iteration still does not converge, then the step size is reduced and a new Jacobian is evaluated. The successive substitution method can also be used—wh ich is even faster, except that it may not converge. However, it too will converge if the time step is small enough.

The Runge – Kutta methods give extremely good accuracy, especially when the step size is kept small for stability reasons. If the problem is stiff, though, backward difference implicit methods must be used. Many chemical reactor problems are stiff, necessitating the use of implicit methods. In the MATLAB suite of ODE solvers, ode45 uses a revision of the RKF45 program, while the ode15s program uses an improved backward difference method. Ref. [64] gives details of the programs in MATLAB. Fortunately, many packages are available. On the NIST web page, http://gams.nist.gov/ choose "problem decision tree", and then "differential and integral equations" to find packages which can be downloaded. On the Netlib web site, http://www.netlib.org/, choose "ode" to find packages which can be downloaded. Using Microsoft Excel to solve ordinary differential equations is cumbersome, except for the simplest problems.

6.7. Stability, Bifurcations, Limit Cycles

In this section, bifurcation theory is discussed in a general way. Some aspects of this subject involve the solution of nonlinear equations; other aspects involve the integration of ordinary differential equations; applications include chaos and fractals as well as unusual operation of some chemical engineering equipment. An excellent introduction to the subject and details needed to apply the methods are given in [65]. For more details of the algorithms described below and a concise survey with some chemical engineering examples, see [66] and [67]. Bifurcation results are closely connected with stability of the steady states, which is essentially a transient phenomenon.

Consider the problem

$$\frac{\partial u}{\partial t} = F\ (u, \lambda)$$

Figure 22. Limit points and bifurcation – limit points
A) Limit point (or turning point); B) Bifurcation-limit point (or singular turning point or bifurcation point)

The variable u can be a vector, which makes F a vector, too. Here, F represents a set of equations that can be solved for the steady state:

$$F\ (u, \lambda) = 0$$

If the Newton – Raphson method is applied,

$$F_u^s\ \delta\ u^s = -F\ (u^s, \lambda)$$

$$u^{s+1} = u^s + \delta u^s$$

is obtained, where

$$F_u^s = \frac{\partial F}{\partial u}\ (u^s)$$

is the Jacobian. Look at some property of the solution, perhaps the value at a certain point or the maximum value or an integral of the solution. This property is plotted versus the parameter λ; typical plots are shown in Figure 22. At the point shown in Figure 22 A, the determinant of the Jacobian is zero:

$$\det F_u = 0$$

For the limit point,

$$\frac{\partial F}{\partial \lambda} \neq 0$$

whereas for the bifurcation-limit point

$$\frac{\partial F}{\partial \lambda} = 0$$

The stability of the steady solutions is also of interest. Suppose a steady solution u_{ss}; the function u is written as the sum of the known steady state and a perturbation u':

$$u = u_{\mathrm{ss}} + u'$$

This expression is substituted into the original equation and linearized about the steady-state value:

$$\frac{\partial u_{\mathrm{ss}}}{\partial t} + \frac{\partial u'}{\partial t} = F\ (u_{\mathrm{ss}} + u', \lambda)$$

$$\approx F\ (u_{\mathrm{ss}}, \lambda) + \frac{\partial F}{\partial u}|_{u_{\mathrm{ss}}} u' + \cdots$$

The result is

$$\frac{\partial u'}{\partial t} = F_u^{\mathrm{ss}}\ u'$$

A solution of the form

$$u'\ (x, t) = \mathrm{e}^{\sigma t}\ X\ (x)$$

gives

$$\sigma \mathrm{e}^{\sigma t}\ X\ = F_u^{\mathrm{ss}} \mathrm{e}^{\sigma t} X$$

The exponential term can be factored out and

$$(F_u^{\mathrm{ss}} - \sigma\ \delta)\ X = 0$$

A solution exists for X if and only if

$$\det\ |F_u^{\mathrm{ss}} - \sigma\ \delta| = 0$$

The σ are the eigenvalues of the Jacobian. Now clearly if Re $(\sigma) > 0$ then u' grows with time, and the steady solution u_{ss} is said to be unstable to small disturbances. If Im $(\sigma) = 0$ it is called stationary instability, and the disturbance would grow monotonically, as indicated in Figure 23 A. If Im $(\sigma) \neq 0$ then the disturbance grows in an oscillatory fashion, as shown in Figure 23 B, and is called oscillatory instability. The case in which Re $(\sigma) = 0$ is the dividing point between stability and instability. If Re $(\sigma) = 0$ and Im $(\sigma) = 0$—the point governing the onset of stationary instability—then $\sigma = 0$. However, this means that $\sigma = 0$ is an eigenvalue of the Jacobian, and the determinant of the Jacobian is zero. Thus, the points at which the determinant of the Jacobian is zero (for limit points

Figure 23. Stationary and oscillatory instability
A) Stationary instability; B) Oscillatory instability

and bifurcation-limit points) are the points governing the onset of stationary instability. When Re (σ) = 0 but Im (σ) $\neq$ 0, which is the onset of oscillatory instability, an even number of eigenvalues pass from the left-hand complex plane to the right-hand complex plane. The eigenvalues are complex conjugates of each other (a result of the original equations being real, with no complex numbers), and this is called a Hopf bifurcation. Numerical methods to study Hopf bifurcation are very computationally intensive and are not discussed here [65].

To return to the problem of solving for the steady-state solution: near the limit point or bifurcation-limit point two solutions exist that are very close to each other. In solving sets of equations with thousands of unknowns, the difficulties in convergence are obvious. For some dependent variables the approximation may be converging to one solution, whereas for another set of dependent variables it may be converging to the other solution; or the two solutions may all be mixed up. Thus, solution is difficult near a bifurcation point, and special methods are required. These methods are discussed in [66].

The first approach is to use *natural continuation* (also known as Euler – Newton continuation). Suppose a solution exists for some parameter λ. Call the value of the parameter λ_0 and the corresponding solution u_0. Then

$$F\ (u_0\ , \lambda_0) = 0$$

Also, compute u_λ as the solution to

$$F_u^{\mathrm{ss}}\ u_\lambda = -F_\lambda$$

at this point [λ_0, u_0]. Then predict the starting guess for another λ using

$$u^0 = u_0 + u_\lambda\ (\lambda - \lambda_0)$$

and apply Newton – Raphson with this initial guess and the new value of λ. This will be a much better guess of the new solution than just u_0 by itself.

Even this method has difficulties, however. Near a limit point the determinant of the Jacobian may be zero and the Newton method may fail. Perhaps no solutions exist at all for the chosen parameter λ near a limit point. Also, the ability to switch from one solution path to another at a bifurcation-limit point is necessary. Thus, other methods are needed as well: arc-length continuation and pseudo-arc-length continuation [66]. These are described in Chapter 1.

6.8. Sensitivity Analysis

Often, when solving differential equations, the solution as well as the sensitivity of the solution to the value of a parameter must be known. Such information is useful in doing parameter estimation (to find the best set of parameters for a model) and in deciding whether a parameter needs to be measured accurately. The differential equation for $y\ (t,\ \alpha)$ where α is a parameter, is

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f\ (y, \alpha)\ ,\ y\ (0) = y_0$$

If this equation is differentiated with respect to α, then because y is a function of t and α

$$\frac{\partial}{\partial \alpha}\left(\frac{\mathrm{d}y}{\mathrm{d}t}\right) = \frac{\partial f}{\partial y}\frac{\partial y}{\partial \alpha} + \frac{\partial f}{\partial \alpha}$$

Exchanging the order of differentiation in the first term leads to the ordinary differential equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial y}{\partial \alpha}\right) = \frac{\partial f}{\partial y}\frac{\partial y}{\partial \alpha}+\frac{\partial f}{\partial \alpha}$$

The initial conditions on $\partial y/\partial\alpha$ are obtained by differentiating the initial conditions

$$\frac{\partial}{\partial \alpha}\left[y\ (0,\alpha) = y_0\right], \text{or } \frac{\partial y}{\partial \alpha}\ (0) = 0$$

Next, let

$$y_1 = y, y_2 = \frac{\partial y}{\partial \alpha}$$

and solve the set of ordinary differential equations

$$\frac{\mathrm{d}y_1}{\mathrm{d}t} = f\ (y_1,\alpha) \qquad y_1\ (0) = y_0$$

$$\frac{\mathrm{d}y_2}{\mathrm{d}t} = \frac{\partial f}{\partial y}\ (y_1,\alpha)\ y_2+\frac{\partial f}{\partial \alpha} \qquad y_2\ (0) = 0$$

Thus, the solution $y\ (t,\ \alpha)$ and the derivative with respect to α are obtained. To project the impact of α, the solution for $\alpha = \alpha_1$ can be used:

$$y\ (t,\alpha) = y_1\ (t,\alpha_1)+\frac{\partial y}{\partial \alpha}\ (t,\alpha_1)\ (\alpha-\alpha_1)+\cdots$$

$$= y_1\ (t,\alpha_1)+y_2\ (t,\alpha_1)\ (\alpha-\alpha_1)+\cdots$$

This is a convenient way to determine the sensitivity of the solution to parameters in the problem.

6.9. Molecular Dynamics

(→ Molecular Dynamics Simulations)
Special integration methods have been developed for molecular dynamics calculations due to the structure of the equations. A very large number of equations are to be integrated, with the following form based on molecular interactions between molecules

$$m_i\frac{d^2\boldsymbol{r}_i}{dt^2}=\boldsymbol{F}_i\ (\{\boldsymbol{r}\}),\boldsymbol{F}_i\ (\{\boldsymbol{r}\})=-\boldsymbol{\nabla}V$$

where m_i is the mass of the i-th particle, $\boldsymbol{r}_i$ is the position of the i-th particle, $\boldsymbol{F}_i$ is the force acting on the i-th particle, and V is the potential energy that depends upon the location of all the particles (but not their velocities). Since the major part of the calculation is in the evaluation of the forces, or potentials, a method must be used that minimizes the number of times the forces are calculated to move from one time to another time. Rewrite this equation in the form of an acceleration.

$$\frac{d^2\boldsymbol{r}_i}{dt^2}=\frac{1}{m_i}\boldsymbol{F}_i\ (\{\boldsymbol{r}\})\equiv\boldsymbol{a}_i$$

In the Verlot method, this equation is written using central finite differences (Eq. 12). Note that the accelerations do not depend upon the velocities.

$$\boldsymbol{r}_i\ (t+\Delta t)=2\boldsymbol{r}_i\ (t)-\boldsymbol{r}_i\ (t-\Delta t)+\boldsymbol{a}_i\ (t)\ \Delta t^2$$

The calculations are straightforward, and no explicit velocity is needed. The storage requirement is modest, and the precision is modest (it is a second-order method). Note that one must start the calculation with values of $\{r\}$ at time t and $t-\Delta t$.

In the Velocity Verlot method, an equation is written for the velocity, too.

$$\frac{d\boldsymbol{v}_i}{dt}=\boldsymbol{a}_i$$

The trapezoid rule (see page 16) is applied to obtain

$$\boldsymbol{v}_i\ (t+\Delta t)=\boldsymbol{v}_i\ (t)+\frac{1}{2}\left[\boldsymbol{a}_i\ (t)+\boldsymbol{a}_i\ (t+\Delta t)\right]\Delta t$$

The position of the particles is expanded in a Taylor series.

$$\boldsymbol{r}_i\ (t+\Delta t)=\boldsymbol{r}_i\ (t)+\boldsymbol{v}_i\Delta t+\frac{1}{2}\boldsymbol{a}_i\ (t)\ \Delta t^2$$

Beginning with values of $\{\boldsymbol{r}\}$ and $\{\boldsymbol{v}\}$ at time zero, one calculates the new positions and then the new velocities. This method is second order in Δt, too. For additional details, see [68 – 72].

7. Ordinary Differential Equations as Boundary Value Problems

Diffusion problems in one dimension lead to boundary value problems. The boundary conditions are applied at two different spatial locations: at one side the concentration may be fixed and at the other side the flux may be fixed. Because the conditions are specified at two different locations the problems are not initial value in character. To begin at one position and integrate directly is impossible because at least one of the conditions is specified somewhere else and not enough conditions are available to begin the

calculation. Thus, methods have been developed especially for boundary value problems. Examples include heat and mass transfer in a slab, reaction – diffusion problems in a porous catalyst, reactor with axial dispersion, packed beds, and countercurrent heat transfer.

7.1. Solution by Quadrature

When only one equation exists, even if it is nonlinear, it may possibly be solved by quadrature. For

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f(y)$$

$$y(0) = y_0$$

the problem can be separated

$$\frac{\mathrm{d}y}{f(y)} = \mathrm{d}t$$

and integrated

$$\int_{y_0}^{y} \frac{dy'}{f(y')} = \int_0^t \mathrm{d}t = t$$

If the quadrature can be performed analytically, the exact solution has been found.

As an example, consider the flow of a non-Newtonian fluid in a pipe, as illustrated in Figure 24. The governing differential equation is [73]

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}(r\tau) = -\frac{\Delta p}{L}$$

where r is the radial position from the center of the pipe, τ is the shear stress, Δp is the pressure drop along the pipe, and L is the length over which the pressure drop occurs. The variables are separated once

$$\mathrm{d}(r\tau) = -\frac{\Delta p}{L} r\mathrm{d}r$$

and then integrated to give

$$r\tau = -\frac{\Delta p}{L}\frac{r^2}{2} + c_1$$

Proceeding further requires choosing a constitutive relation relating the shear stress and the velocity gradient as well as a condition specifying the constant. For a Newtonian fluid

$$\tau = -\eta\frac{\mathrm{d}v}{\mathrm{d}r}$$

where v is the velocity and η the viscosity. Then the variables can be separated again and the result integrated to give

$$-\eta v = -\frac{\Delta p}{L}\frac{r^2}{4} + c_1 \ln r + c_2$$

Now the two unknowns must be specified from the boundary conditions. This problem is a two-point boundary value problem because one of the conditions is usually specified at $r = 0$ and the other at $r = R$, the tube radius. However, the technique of separating variables and integrating works quite well.

Figure 24. Flow in pipe

When the fluid is non-Newtonian, it may not be possible to do the second step analytically. For example, for the Bird – Carreau fluid [74, p. 171], stress and velocity are related by

$$\tau = \frac{\eta_0}{\left[1+\lambda\left(\frac{\mathrm{d}v}{\mathrm{d}r}\right)^2\right]^{(1-n)/2}}$$

where η_0 is the viscosity at $v = 0$ and λ the time constant.

Putting this value into the equation for stress as a function of r gives

$$\frac{\eta_0}{\left[1+\lambda\left(\frac{\mathrm{d}v}{\mathrm{d}r}\right)^2\right]^{(1-n)/2}} = -\frac{\Delta p}{L}\frac{r}{2} + \frac{c_1}{r}$$

This equation cannot be solved analytically for $\mathrm{d}v/\mathrm{d}r$, except for special values of n. For problems such as this, numerical methods must be used.

7.2. Initial Value Methods

An initial value method is one that utilizes the techniques for initial value problems but allows for an iterative calculation to satisfy all the boundary conditions. Suppose the nonlinear boundary value problem

$$\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} = f\left(x, y, \frac{\mathrm{d}y}{\mathrm{d}x}\right)$$

with the boundary conditions

$$a_0\, y\,(0) - a_1 \tfrac{\mathrm{d}y}{\mathrm{d}x}\,(0) = \alpha,\ a_{\mathrm{i}} \geq 0$$

$$b_0\, y\,(1) - b_1 \tfrac{\mathrm{d}y}{\mathrm{d}x}\,(1) = \beta,\ b_{\mathrm{i}} \geq 0$$

Convert this second-order equation into two first-order equations along with the boundary conditions written to include a parameter s.

$$\tfrac{\mathrm{d}u}{\mathrm{d}x} = v$$

$$\tfrac{\mathrm{d}v}{\mathrm{d}x} = f\,(x, u, v)$$

$$u\,(0) = a_1 s - c_1 \alpha$$

$$v\,(0) = a_0 s - c_0 \alpha$$

The parameters c_0 and c_1 are specified by the analyst such that

$$a_1 c_0 - a_0 c_1 = 1$$

This ensures that the first boundary condition is satisfied for any value of parameter s. If the proper value for s is known, u (0) and u' (0) can be evaluated and the equation integrated as an initial value problem. The parameter s should be chosen iteratively so that the last boundary condition is satisfied.

The model for a *chemical reactor with axial diffusion* is

$$\tfrac{1}{Pe}\tfrac{\mathrm{d}c^2}{\mathrm{d}z^2} - \tfrac{\mathrm{d}c}{\mathrm{d}z} = DaR\,(c)$$

$$-\tfrac{1}{Pe}\tfrac{\mathrm{d}c}{\mathrm{d}z}\,(0) + c\,(0) = c_{\mathrm{in}},\ \tfrac{\mathrm{d}c}{\mathrm{d}z}\,(1) = 0$$

where Pe is the Péclet number and Da the Damköhler number.

The boundary conditions are due to Danckwerts [75] and to Wehner and Wilhelm [76]. This problem can be treated by using initial value methods also, but the method is highly sensitive to the choice of the parameter s, as outlined above. Starting at $z = 0$ and making small changes in s will cause large changes in the solution at the exit, and the boundary condition at the exit may be impossible to satisfy. By starting at $z = 1$, however, and integrating backwards, the process works and an iterative scheme converges in many cases [77]. However, if the problem is extremely nonlinear the iterations may not converge. In such cases, the methods for boundary value problems described below must be used.

Packages to solve boundary value problems are available on the internet. On the NIST web page, http://gams.nist.gov/ choose "problem decision tree", and then "differential and integral equations", then "ordinary differential equations", "multipoint boundary value problems". On the Netlib web site, http://www.netlib.org/, search on "boundary value problem". Any spreadsheet that has an iteration capability can be used with the finite difference method. Some packages for partial differential equations also have a capability for solving one-dimensional boundary value problems [e.g., Comsol Multiphysics (formerly FEMLAB)].

7.3. Finite Difference Method

To apply the finite difference method, we first spread grid points through the domain. Figure 25 shows a uniform mesh of n points (nonuniform meshes are also possible). The unknown, here $c\,(x)$, at a grid point x_i is assigned the symbol $c_i = c\,(x_i)$. The finite difference method can be derived easily by using a Taylor expansion of the solution about this point.

$$\begin{aligned} c_{i+1} &= c_i + \left.\tfrac{\mathrm{d}c}{\mathrm{d}x}\right|_i \Delta x + \left.\tfrac{\mathrm{d}^2 c}{\mathrm{d}x^2}\right|_i \tfrac{\Delta x^2}{2} + \ldots \\ c_{i-1} &= c_i - \left.\tfrac{\mathrm{d}c}{\mathrm{d}x}\right|_i \Delta x + \left.\tfrac{\mathrm{d}^2 c}{\mathrm{d}x^2}\right|_i \tfrac{\Delta x^2}{2} - \ldots \end{aligned} \tag{8}$$

These formulas can be rearranged and divided by Δx to give

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i = \frac{c_{i+1} - c_i}{\Delta x} - \left.\frac{\mathrm{d}^2 c}{\mathrm{d}x^2}\right|_i \frac{\Delta x}{2} + \ldots \tag{9}$$

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i = \frac{c_i - c_{i-1}}{\Delta x} - \left.\frac{\mathrm{d}^2 c}{\mathrm{d}x^2}\right|_i \frac{\Delta x}{2} + \ldots \tag{10}$$

which are representations of the first derivative. Alternatively the two equations can be subtracted from each other, rearranged and divided by Δx to give

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i = \frac{c_{i+1} - c_{i-1}}{2\Delta x} - \left.\frac{\mathrm{d}^2 c}{\mathrm{d}x^3}\right|_i \frac{\Delta x^2}{3!} \tag{11}$$

If the terms multiplied by Δx or Δx^2 are neglected, three representations of the first derivative are possible. In comparison with the Taylor series, the truncation error in the first two expressions is proportional to Δx, and the methods are said to be first order. The truncation error in the last expression is proportional to Δx^2, and the method is said to be second order. Usually, the

last equation is chosen to ensure the best accuracy.

Figure 25. Finite difference mesh; Δx uniform

The finite difference representation of the second derivative can be obtained by adding the two expressions in Equation 8. Rearrangement and division by Δx^2 give

$$\left.\frac{\mathrm{d}^2c}{\mathrm{d}x^2}\right|_i = \frac{c_{i+1}-2_{ci}+c_{i-1}}{\Delta x^2} - \left.\frac{\mathrm{d}^4c}{\mathrm{d}x^4}\right|_i \frac{\Delta x^2}{4!} + \ldots \tag{12}$$

The truncation error is proportional to Δx^2.

To see how to solve a differential equation, consider the equation for convection, diffusion, and reaction in a tubular reactor:

$$\frac{1}{Pe}\frac{\mathrm{d}^2c}{\mathrm{d}x^2} - \frac{\mathrm{d}c}{\mathrm{d}x} = Da\,R\,(c)$$

To evaluate the differential equation at the i-th grid point, the finite difference representations of the first and second derivatives can be used to give

$$\frac{1}{Pe}\frac{c_{i+1}-2c_i+c_{i-1}}{\Delta x^2} - \frac{c_{i+1}-c_{i-1}}{2\Delta x} = Da\,R \tag{13}$$

This equation is written for $i = 2$ to $n - 1$ (i.e., the internal points). The equations would then be coupled but would involve the values of c_1 and c_n, as well. These are determined from the boundary conditions.

If the boundary condition involves a derivative, the finite difference representation of it must be carefully selected; here, three possibilities can be written. Consider a derivative needed at the point $i = 1$. First, Equation 9 could be used to write

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_1 = \frac{c_2-c_1}{\Delta x} \tag{14}$$

Then a second-order expression is obtained that is one-sided. The Taylor series for the point c_{i+2} is written:

$$c_{i+2} = c_i + \left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i 2\Delta x + \left.\frac{\mathrm{d}^2c}{\mathrm{d}x^2}\right|_i \frac{4\Delta x^2}{2!}$$
$$+ \left.\frac{\mathrm{d}^3c}{\mathrm{d}x^3}\right|_i \frac{8\Delta x^3}{3!} + \ldots$$

Four times Equation 8 minus this equation, with rearrangement, gives

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i = \frac{-3c_i+4c_{i+1}-c_{i+2}}{2\Delta x} + O\left(\Delta x^2\right)$$

Thus, for the first derivative at point $i = 1$

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_i = \frac{-3c_i+4c_2-c_3}{2\Delta x} \tag{15}$$

This one-sided difference expression uses only the points already introduced into the domain. The third alternative is to add a false point, outside the domain, as $c_0 = c\ (x = -\Delta x)$. Then the centered first derivative, Equation 11, can be used:

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_1 = \frac{c_2-c_0}{2\Delta x}$$

Because this equation introduces a new variable, another equation is required. This is obtained by also writing the differential equation (Eq. 13), for $i = 1$.

The same approach can be taken at the other end. As a boundary condition, any of three choices can be used:

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_n = \frac{c_n-c_{n-1}}{\Delta x}$$

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_n = \frac{c_{n-2}-4c_{n-1}+3c_n}{2\Delta x}$$

$$\left.\frac{\mathrm{d}c}{\mathrm{d}x}\right|_n = \frac{c_{n+1}-c_{n-1}}{2\Delta x}$$

The last two are of order Δx^2 and the last one would require writing the differential equation (Eq. 13) for $i = n$, too.

Generally, the first-order expression for the boundary condition is not used because the error in the solution would decrease only as Δx, and the higher truncation error of the differential equation (Δx^2) would be lost. For this problem the boundary conditions are

$$-\frac{1}{Pe}\frac{\mathrm{d}c}{\mathrm{d}x}(0) + c(0) = c_{\mathrm{in}}$$

$$\frac{\mathrm{d}c}{\mathrm{d}x}(1) = 0$$

Thus, the three formulations would give first order in Δx

$$-\frac{1}{Pe}\frac{c_2-c_1}{\Delta x} + c_1 = c_{\mathrm{in}}$$

$$\frac{c_n-c_{n-1}}{\Delta x} = 0$$

plus Equation 13 at points $i = 2$ through $n - 1$; second order in Δx, by using a three-point one-sided derivative

$$-\frac{1}{Pe}\frac{-3c_1+4c_2-c_3}{2\Delta x}+c_1=c_{\text{in}}$$

$$\frac{c_{n-2}-4c_{n-1}+3c_n}{2\Delta x}=0$$

plus Equation 13 at points $i = 2$ through $n - 1$; second order in Δx, by using a false boundary point

$$-\frac{1}{Pe}\frac{c_2-c_0}{2\Delta x}+c_1=c_{\text{in}}$$

$$\frac{c_{n+1}-c_{n-1}}{2\Delta x}=0$$

plus Equation 13 at points $i = 1$ through n.

The sets of equations can be solved by using the Newton – Raphson method, as outlined in Section 1.2.

Frequently, the transport coefficients (e.g., diffusion coefficient D or thermal conductivity) depend on the dependent variable (concentration or temperature, respectively). Then the differential equation might look like

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(D(c)\frac{\mathrm{d}c}{\mathrm{d}x}\right)=0$$

This could be written as

$$-\frac{\mathrm{d}J}{\mathrm{d}x}=0 \tag{16}$$

in terms of the mass flux J, where the mass flux is given by

$$J=-D(c)\frac{\mathrm{d}c}{\mathrm{d}x}$$

Because the coefficient depends on c the equations are more complicated. A finite difference method can be written in terms of the fluxes at the midpoints, $i + 1/2$. Thus,

$$-\frac{J_{i+1/2}-J_{i-1/2}}{\Delta x}=0$$

Then the constitutive equation for the mass flux can be written as

$$J_{i+1/2}=-D\left(c_{i+1/2}\right)\frac{c_{i+1}-c_i}{\Delta x}$$

If these are combined,

$$\frac{D\left(c_{i+1/2}\right)\left(c_{i+1}-c_i\right)-D\left(c_{i-1/2}\right)\left(c_i-c_{i-1}\right)}{\Delta x^2}=0$$

This represents a set of nonlinear algebraic equations that can be solved with the Newton – Raphson method. However, in this case a viable iterative strategy is to evaluate the transport coefficients at the last value and then solve

$$\frac{D\left(c_{i+1/2}^k\right)\left(c_{i+1}^{k+1}-c_i^{k+1}\right)-D\left(c_{i-1/2}^k\right)\left(c_i^{k+1}-c_{i-1}^{k+1}\right)}{\Delta x^2}=0$$

The advantage of this approach is that it is easier to program than a full Newton – Raphson method. If the transport coefficients do not vary radically, the method converges. If the method does not converge, use of the full Newton – Raphson method may be necessary.

Three ways are commonly used to evaluate the transport coefficient at the midpoint. The first one employs the transport coefficient evaluated at the average value of the solutions on either side:

$$D\left(c_{i+1/2}\right)\approx D\left[\frac{1}{2}\left(c_{i+1}+c_i\right)\right]$$

The second approach uses the average of the transport coefficients on either side:

$$D\left(c_{i+1/2}\right)\approx\frac{1}{2}\left[D\left(c_{i+1}\right)+D\left(c_i\right)\right] \tag{17}$$

The truncation error of these approaches is also Δx^2 [78, Chap. 14], [3, p. 215]. The third approach employs an "upstream" transport coefficient.

$$D\left(C_{i+1/2}\right)\approx D\left(c_{i+1}\right),\ \text{when } D\left(c_{i+1}\right)>D\left(c_i\right)$$

$$D\left(c_{i+1/2}\right)\approx\left(c_i\right),\ \text{when } D\left(c_{i+1}\right)<D\left(c_i\right)$$

This approach is used when the transport coefficients vary over several orders of magnitude and the "upstream" direction is defined as the one in which the transport coefficient is larger. The truncation error of this approach is only Δx [78, Chap. 14] , [3, p. 253], but this approach is useful if the numerical solutions show unrealistic oscillations [3, 78].

Rigorous error bounds for linear ordinary differential equations solved with the finite difference method are dicussed by Isaacson and Keller [79, p. 431].

7.4. Orthogonal Collocation

The orthogonal collocation method has found widespread application in chemical engineering, particularly for chemical reaction engineering. In the collocation method [3], the dependent variable is expanded in a series.

$$y(x)=\sum_{i=1}^{N+2}a_iy_i(x) \tag{18}$$

Suppose the differential equation is

$$N[y] = 0$$

Then the expansion is put into the differential equation to form the residual:

$$\text{Residual} = N\left[\sum_{i=1}^{N+2} a_i y_i(x)\right]$$

In the collocation method, the residual is set to zero at a set of points called collocation points:

$$N\left[\sum_{i=1}^{N+2} a_i y_i(x_j)\right] = 0,\ j = 2,\ldots,N+1$$

This provides N equations; two more equations come from the boundary conditions, giving $N + 2$ equations for $N + 2$ unknowns. This procedure is especially useful when the expansion is in a series of orthogonal polynomials, and when the collocation points are the roots to an orthogonal polynomial, as first used by Lanczos [80, 81]. A major improvement was the proposal by Villadsen and Stewart [82] that the entire solution process be done in terms of the solution at the collocation points rather than the coefficients in the expansion. Thus, Equation 18 would be evaluated at the collocation points

$$y(x_j) = \sum_{i=1}^{N+2} a_i y_i(x_j),\ j = 1,\ldots,N+2$$

and solved for the coefficients in terms of the solution at the collocation points:

$$a_i = \sum_{j=1}^{N+2} [y_i(x_j)]^{-1}\, y(x_j),\ i = 1,\ldots,N+2$$

Furthermore, if Equation 18 is differentiated once and evaluated at all collocation points, the first derivative can be written in terms of the values at the collocation points:

$$\frac{\mathrm{d}y}{\mathrm{d}x}(x_j) = \sum_{i=1}^{N+2} a_i \frac{\mathrm{d}y_i}{\mathrm{d}x}(x_j),\ j = 1,\ldots,N+2$$

This can be expressed as

$$\frac{\mathrm{d}y}{\mathrm{d}x}(x_j) = \sum_{i,k=1}^{N+2} [y_i(x_k)]^{-1}\, y(x_k)\, \frac{\mathrm{d}y_i}{\mathrm{d}x}(x_j),\ j = 1,\ldots,N+2$$

or shortened to

$$\frac{\mathrm{d}y}{\mathrm{d}x}(x_j) = \sum_{k=1}^{N+2} A_{jk}\, y(x_k),$$

$$A_{jk} = \sum_{i=1}^{N+2} [y_i(x_k)]^{-1} \frac{\mathrm{d}y_i}{\mathrm{d}x}(x_j)$$

Similar steps can be applied to the second derivative to obtain

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}(x_j) = \sum_{k=1}^{N+2} B_{jk}\, y(x_k),$$

$$B_{jk} = \sum_{i=1}^{N+2} [y_i(x_k)]^{-1} \frac{\mathrm{d}^2y_i}{\mathrm{d}x^2}(x_j)$$

This method is next applied to the differential equation for reaction in a tubular reactor, after the equation has been made nondimensional so that the dimensionless length is 1.0.

$$\begin{aligned} &\frac{1}{Pe}\frac{\mathrm{d}^2c}{\mathrm{d}x^2} - \frac{\mathrm{d}c}{\mathrm{d}x} = Da\, R(c), \\ &-\frac{\mathrm{d}c}{\mathrm{d}x}(0) = Pe\,[c(0) - c_{\text{in}}],\ \frac{\mathrm{d}c}{\mathrm{d}x}(1) = 0 \end{aligned} \tag{19}$$

The differential equation at the collocation points is

$$\frac{1}{Pe}\sum_{k=1}^{N+2} B_{jk}\, c(x_k) - \sum_{k=1}^{N+2} A_{jk}\, c(x_k) = Da\, R(c_j) \tag{20}$$

and the two boundary conditions are

$$\begin{aligned} &-\sum_{k=1}^{N+2} A_{lk}\, c(x_k) = Pe\,(c_1 - c_{\text{in}}), \\ &\sum_{k=1}^{N+2} A_{N+2,k}\, c(x_k) = 0 \end{aligned} \tag{21}$$

Note that 1 is the first collocation point ($x = 0$) and $N + 2$ is the last one ($x = 1$). To apply the method, the matrices A_{ij} and B_{ij} must be found and the set of algebraic equations solved, perhaps with the Newton – Raphson method. If orthogonal polynomials are used and the collocation points are the roots to one of the orthogonal polynomials, the orthogonal collocation method results.

In the orthogonal collocation method the solution is expanded in a series involving orthogonal polynomials, where the polynomials $P_{i-1}(x)$ are defined in Section 2.2.

$$\begin{aligned} y &= a + bx + x(1-x)\sum_{i=1}^{N} a_i P_{i-1}(x) \\ &= \sum_{i=1}^{N+2} b_i P_{i-1}(x) \end{aligned} \tag{22}$$

which is also

$$y = \sum_{i=1}^{N+2} d_i x^{i-1}$$

Figure 26. Orthogonal collocation points

The collocation points are shown in Figure 26. There are N interior points plus one at each end, and the domain is always transformed to lie on 0 to 1. To define the matrices A_{ij} and B_{ij} this expression is evaluated at the collocation points; it is also differentiated and the result is evaluated at the collocation points.

$$y\left(x_j\right)=\sum_{i=1}^{N+2} d_i x_j^{i-1}$$

$$\frac{\mathrm{d}y}{\mathrm{d}x}\left(x_j\right)=\sum_{i=1}^{N+2} d_i\left(i-1\right) x_j^{i-2}$$

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}\left(x_j\right)=\sum_{i=1}^{N+2} d_i\left(i-1\right)\left(i-2\right) x_j^{i-3}$$

These formulas are put in matrix notation, where $\boldsymbol{Q}$, $\boldsymbol{C}$, and $\boldsymbol{D}$ are $N+2$ by $N+2$ matrices.

$$\boldsymbol{y}=\boldsymbol{Q}\boldsymbol{d}, \frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}x}=\boldsymbol{C}\boldsymbol{d}, \frac{\mathrm{d}^2\boldsymbol{y}}{\mathrm{d}x^2}=\boldsymbol{D}\boldsymbol{d}$$

$$Q_{ji}=x_j^{i-1},\ C_{ji}=\left(i-1\right) x_j^{i-2},$$

$$D_{ji}=\left(i-1\right)\left(i-2\right) x_j^{i-3}$$

In solving the first equation for $\boldsymbol{d}$, the first and second derivatives can be written as

$$\boldsymbol{d}=\boldsymbol{Q}^{-1}\boldsymbol{y},\ \frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}x}=\boldsymbol{C}\boldsymbol{Q}^{-1}\boldsymbol{y}=\boldsymbol{A}\boldsymbol{y},$$
$$\frac{\mathrm{d}^2\boldsymbol{y}}{\mathrm{d}x^2}=\boldsymbol{D}\boldsymbol{Q}^{-1}\boldsymbol{y}=\boldsymbol{B}\boldsymbol{y} \tag{23}$$

Thus the derivative at any collocation point can be determined in terms of the solution at the collocation points. The same property is enjoyed by the finite difference method (and the finite element method described below), and this property accounts for some of the popularity of the orthogonal collocation method. In applying the method to Equation 19, the same result is obtained; Equations 20 and 21, with the matrices defined in Equation 23. To find the solution at a point that is not a collocation point, Equation 22 is used; once the solution is known at all collocation points, $\boldsymbol{d}$ can be found; and once $\boldsymbol{d}$ is known, the solution for any x can be found.

To use the orthogonal collocation method, the matrices are required. They can be calculated as shown above for small N ($N<8$) and by using more rigorous techniques, for higher N (see Chap. 2). However, having the matrices listed explicitly for $N=1$ and 2 is useful; this is shown in Table 7.

For some reaction diffusion problems, the solution can be an even function of x. For example, for the problem

$$\frac{\mathrm{d}^2c}{\mathrm{d}x^2}=kc,\ \frac{\mathrm{d}c}{\mathrm{d}x}\left(0\right)=0,\ c\left(1\right)=1 \tag{24}$$

the solution can be proved to involve only even powers of x. In such cases, an orthogonal collocation method, which takes this feature into

Table 7. Matrices for orthogonal collocation

$N=1, a=0.1666666667$

$$x_j=\begin{pmatrix}0\\0.5\\1\end{pmatrix}, W_j=\begin{pmatrix}a\\4\,a\\a\end{pmatrix}, A_{ji}=\begin{pmatrix}-3&4&-1\\-1&0&1\\1&-4&3\end{pmatrix}, B_{ji}=\begin{pmatrix}4&-8&4\\4&-8&4\\4&-8&4\end{pmatrix}, Q_{ji}^{-1}=\begin{pmatrix}1&0&0\\-3&4&-1\\2&-4&2\end{pmatrix}$$

$N=2$

$$x_j=\begin{pmatrix}0\\e\\1-e\\1\end{pmatrix}, W_j=\begin{pmatrix}0\\0.5\\0.5\\0\end{pmatrix}, Q_{ji}^{-1}=\begin{pmatrix}1&0&0&0\\-7&7+b&-1-b&1\\12&-18-f&12+f&-6\\-6&10+d&-10-d&6\end{pmatrix}$$

$$A_{ji}=\begin{pmatrix}-7&7+b&-1-b&1\\-1-a&a&a&1-a\\-1+a&-a&-a&1+a\\-1&1+b&-7-b&7\end{pmatrix}, B_{ji}=\begin{pmatrix}24&-37-c&25+c&-12\\16+d&-24&12&-4-d\\-4-d&12&-24&16+d\\-12&25+c&-37-c&24\end{pmatrix}$$

where $a=1.732050808$, $b=1.196152423$, $c=0.17691454$, $d=0.392304846$
$e=0.2113248654$, $f=0.58845727$

account, is convenient. This can easily be done by using expansions that only involve even powers of x. Thus, the expansion

$$y\left(x^2\right) = y\left(1\right) + \left(1-x^2\right)\sum_{i=1}^{N} a_i P_{i-1}\left(x^2\right)$$

is equivalent to

$$y\left(x^2\right) = \sum_{i=1}^{N+1} b_i P_{i-1}\left(x^2\right) = \sum_{i=1}^{N+1} d_i x^{2i-2}$$

The polynomials are defined to be orthogonal with the weighting function $W\left(x^2\right)$.

$$\int_0^1 W\left(x^2\right) P_k\left(x^2\right) P_m\left(x^2\right) x^{a-1}\mathrm{d}x = 0 \qquad k \le m-1 \tag{25}$$

where the power on x^{a-1} defines the geometry as planar or Cartesian ($a = 1$), cylindrical ($a = 2$), and spherical ($a = 3$). An analogous development is used to obtain the $(N + 1)\times(N + 1)$ matrices

$$y\left(x_j\right) = \sum_{i=1}^{N+1} d_i x_j^{2i-2}$$

$$\frac{\mathrm{d}y}{\mathrm{d}x}\left(x_j\right) = \sum_{i=1}^{N+1} d_i\left(2i-2\right) x_j^{2i-3}$$

$$\nabla^2 y\left(x_i\right) = \sum_{i=1}^{N+1} d_i \nabla^2\left(x^{2i-2}\right)\Big|_{x_j}$$

$$\boldsymbol{y} = \boldsymbol{Q}\boldsymbol{d}, \frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}x} = \boldsymbol{C}\boldsymbol{d}, \nabla^2\boldsymbol{y} = \boldsymbol{D}\boldsymbol{d}$$

$$Q_{ji} = x_j^{2i-2},\ C_{ji} = \left(2i-2\right) x_j^{2i-3},$$

$$D_{ji} = \nabla^2\left(x^{2i-2}\right)|_{x_j}$$

$$\boldsymbol{d} = \boldsymbol{Q}^{-1}\boldsymbol{y}, \frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}x} = \boldsymbol{C}\boldsymbol{Q}^{-1}\boldsymbol{y} = \boldsymbol{A}\boldsymbol{y},$$

$$\nabla^2\boldsymbol{y} = \boldsymbol{D}\boldsymbol{Q}^{-1}\boldsymbol{y} = \boldsymbol{B}\boldsymbol{y}$$

In addition, the quadrature formula is

$$\boldsymbol{W}\boldsymbol{Q} = \boldsymbol{f},\ \boldsymbol{W} = \boldsymbol{f}\boldsymbol{Q}^{-1}$$

where

$$\int_0^1 x^{2i-2} x^{a-1}\mathrm{d}x = \sum_{j=1}^{N+1} W_j x_j^{2i-2} = \frac{1}{2i-2+a} \equiv f_i$$

As an example, for the problem

$$\frac{1}{x^{a-1}}\frac{\mathrm{d}}{\mathrm{d}x}\left(x^{a-1}\frac{\mathrm{d}c}{\mathrm{d}x}\right) = \varphi^2 R\left(c\right)$$

$$\frac{\mathrm{d}c}{\mathrm{d}x}\left(0\right) = 0,\ c\left(1\right) = 1$$

orthogonal collocation is applied at the interior points

$$\sum_{i=1}^{N+1} B_{ji} c_i = \varphi^2 R\left(c_j\right),\ j = 1,\ldots,N$$

and the boundary condition solved for is

$$c_{N+1} = 1$$

The boundary condition at $x = 0$ is satisfied automatically by the trial function. After the solution has been obtained, the effectiveness factor η is obtained by calculating

$$\eta \equiv \frac{\int_0^1 R\left[c\left(x\right)\right] x^{a-1}\mathrm{d}x}{\int_0^1 R\left[c\left(1\right)\right] x^{a-1}\mathrm{d}x} = \frac{\sum_{i=1}^{N+1} W_j R\left(c_j\right)}{\sum_{i=1}^{N+1} W_j R\left(1\right)}$$

Note that the effectiveness factor is the average reaction rate divided by the reaction rate evaluated at the external conditions. Error bounds have been given for linear problems [83, p. 356]. For planar geometry the error is

$$\text{Error in } \eta = \frac{\varphi^{2(2N+1)}}{\left(2N+1\right)!\left(2N+2\right)!}$$

This method is very accurate for small N (and small φ^2); note that for finite difference methods the error goes as $1/N^2$, which does not decrease as rapidly with N. If the solution is desired at the center (a frequent situation because the center concentration can be the most extreme one), it is given by

$$c\left(0\right) = d_1 \sum_{i=1}^{N+1}\left[Q^{-1}\right]_{1i} y_i$$

The collocation points are listed in Table 8. For small N the results are usually more accurate when the weighting function in Equation 25 is $1 - x^2$. The matrices for $N = 1$ and $N = 2$ are given in Table 9 for the three geometries. Computer programs to generate matrices and a program to solve reaction diffusion problems, OCRXN, are available [3, p. 325, p. 331].

Orthogonal collocation can be applied to distillation problems. Stewart et al. [84, 85] developed a method using Hahn polynomials that retains the discrete nature of a plate-to-plate distillation column. Other work treats problems with multiple liquid phases [86]. Some of the applications to chemical engineering can be found in [87 – 90].

7.5. Orthogonal Collocation on Finite Elements

In the method of orthogonal collocation on finite elements, the domain is first divided into elements, and then within each element orthogonal collocation is applied. Figure 27 shows the domain being divided into *NE* elements, with *NCOL* interior collocation points within each element, and *NP* = *NCOL* + 2 total points per element, giving *NT* = *NE* * (*NCOL* + 1) + 1 total number of points. Within each element a local coordinate is defined

$$u = \frac{x - x_{(k)}}{\Delta x_k},\ \Delta x_k = x_{(k+1)} - x_{(k)}$$

The reaction – diffusion equation is written as

$$\frac{1}{x^{a-1}} \frac{\mathrm{d}}{\mathrm{d}x} \left(x^{a-1} \frac{\mathrm{d}c}{\mathrm{d}x} \right) = \frac{\mathrm{d}^2 c}{\mathrm{d}x^2} + \frac{a-1}{x} \frac{\mathrm{d}c}{\mathrm{d}x} = \varphi^2 R(c)$$

and transformed to give

$$\frac{1}{\Delta x_k^2} \frac{\mathrm{d}^2}{\mathrm{d}u^2} + \frac{a-1}{x_{(k)} + u \Delta x_k} \frac{1}{\Delta x_k} \frac{\mathrm{d}c}{\mathrm{d}u} = \varphi^2 R(c)$$

The boundary conditions are typically

$$\frac{\mathrm{d}c}{\mathrm{d}x}(0) = 0,\ -\frac{\mathrm{d}c}{\mathrm{d}x}(1) = Bi_m \left[c(1) - c_B \right]$$

where Bi_m is the Biot number for mass transfer. These become

$$\frac{1}{\Delta x_1} \frac{\mathrm{d}c}{\mathrm{d}u}(u = 0) = 0,$$

in the first element;

$$-\frac{1}{\Delta x_{N\ E}} \frac{\mathrm{d}c}{\mathrm{d}u}(u = 1) = Bi_m \left[c(u = 1) - c_B \right],$$

in the last element. The orthogonal collocation method is applied at each interior collocation point.

$$\frac{1}{\Delta x_k^2} \sum_{J=1}^{N\ P} B_{I\ J} c_J + \frac{a-1}{x_{(k)} + u_I \Delta x_k} \frac{1}{\Delta x_k} \sum_{J=1}^{N\ P} A_{I\ J} c_J = \\ = \varphi^2 R(c_J),\ I = 2, \ldots, N\ P - 1$$

The local points $i = 2, \ldots, NP - 1$ represent the interior collocation points. Continuity of the function and the first derivative between elements is achieved by taking

$$\frac{1}{\Delta x_{k-1}} \sum_{J=1}^{N\ P} A_{N\ P,J} c_J \Big|_{\text{element } k-1} \\ = \frac{1}{\Delta x_k} \sum_{J=1}^{N\ P} A_{1,J} c_J \Big|_{\text{element } k}$$

at the points between elements. Naturally, the computer code has only one symbol for the solution at a point shared between elements, but the derivative condition must be imposed. Finally, the boundary conditions at $x = 0$ and $x = 1$ are applied:

$$\frac{1}{\Delta x_k} \sum_{J=1}^{N\ P} A_{1,J} c_J = 0,$$

in the first element;

$$-\frac{1}{\Delta x_{N\ E}} \sum_{J=1}^{N\ P} A_{N\ P,J} c_J = Bi_m \left[c_{NP} - c_B \right],$$

in the last element.

These equations can be assembled into an overall matrix problem

$$\boldsymbol{A}\ \boldsymbol{A}\boldsymbol{c} = \boldsymbol{f}$$

$$B_{ji} = \begin{pmatrix} -6 & 6 \\ -6 & 6 \end{pmatrix}, \quad Q_{ji}^{-1} = \begin{pmatrix} 1.5 & -0.5 \\ -1.5 & 1.5 \end{pmatrix}$$

$N = 2$

$$x_j = \begin{pmatrix} 0.39377 \\ 0.80309 \\ 1.000000 \end{pmatrix}, \quad W_j = \begin{pmatrix} 0.18820 \\ 0.25624 \\ 0.05555 \end{pmatrix}, \quad A_{ji} = \begin{pmatrix} -2.53958 & 3.82562 & -1.28603 \\ -1.37768 & -1.24519 & 2.62287 \\ 1.71548 & -9.71548 & 8.00000 \end{pmatrix}$$

$$B_{ji} = \begin{pmatrix} -9.90238 & 12.29966 & -2.39728 \\ 9.03367 & -32.76429 & 23.73061 \\ 22.7575 & -65.42415 & 42.66667 \end{pmatrix}, \quad Q_{ji}^{-1} = \begin{pmatrix} 1.58808 & -0.89141 & 0.33333 \\ -3.97389 & 6.64056 & -2.66667 \\ 2.41582 & -5.74914 & 3.33333 \end{pmatrix}$$

Spherical geometry, $a = 3$

$N = 1$

$$x_j = \begin{pmatrix} 0.654654 \\ 1.000000 \end{pmatrix}, \quad W_j = \begin{pmatrix} 0.233333 \\ 0.100000 \end{pmatrix}, \quad A_{ji} = \begin{pmatrix} -2.291288 & 2.291288 \\ -3.500000 & 3.500000 \end{pmatrix}$$

$$B_{ji} = \begin{pmatrix} -10.5 & 10.5 \\ -10.5 & 10.5 \end{pmatrix}, \quad Q_{ji}^{-1} = \begin{pmatrix} 1.75 & -0.75 \\ -1.75 & 1.75 \end{pmatrix}$$

$N = 2$

$$x_j = \begin{pmatrix} 0.46885 \\ 0.83022 \\ 1.00000 \end{pmatrix}, \quad W_j = \begin{pmatrix} 0.09491 \\ 0.19081 \\ 0.04762 \end{pmatrix}, \quad A_{ji} = \begin{pmatrix} -3.19933 & 5.01517 & -1.81584 \\ -1.40870 & -1.80674 & 3.21544 \\ 1.69677 & -10.69677 & 9.00000 \end{pmatrix}$$

$$B_{ji} = \begin{pmatrix} -15.66996 & 20.03488 & -4.36492 \\ 9.96512 & -44.33004 & 34.36492 \\ 26.93285 & -86.93229 & 60.00000 \end{pmatrix}, \quad Q_{ji}^{-1} = \begin{pmatrix} 1.88193 & -1.50693 & 0.625 \\ -4.61225 & 8.36225 & -3.750 \\ 2.73032 & -6.85532 & 4.125 \end{pmatrix}$$

The form of these equations is special and is discussed by FINLAYSON [3, p. 116], who also gives the computer code to solve linear equations arising in such problems. Reaction – diffusion problems are solved by the program OCFERXN [3, p. 337]. See also the program COLSYS described below.

The error bounds of DEBOOR [91] give the following results for second-order problems solved with cubic trial functions on finite elements with

Figure 27. Grid for orthogonal collocation on finite elements

continuous first derivatives. The error at all positions is bounded by

$$\left\| \frac{\mathrm{d}^i}{\mathrm{d}x^i} \left(y - y_{\text{exact}}\right) \right\|_\infty \leq \text{constant} |\Delta x|^2$$

The error at the collocation points is more accurate, giving what is known as superconvergence.

$$\left| \frac{\mathrm{d}^i}{\mathrm{d}x^i} \left(y - y_{\text{exact}}\right) \right|_{\text{collocation points}} \leq \text{constant} |\Delta x|^4$$

7.6. Galerkin Finite Element Method

In the finite element method the domain is divided into elements and an expansion is made for the solution on each finite element. In the Galerkin finite element method an additional idea is introduced: the Galerkin method is used to solve the equation. The Galerkin method is explained before the finite element basis set is introduced.

To solve the problem

$$\frac{1}{x^{a-1}} \frac{\mathrm{d}}{\mathrm{d}x} \left(x^{a-1} \frac{\mathrm{d}c}{\mathrm{d}x} \right) = \varphi^2 R(c)$$

$$\frac{\mathrm{d}c}{\mathrm{d}x}(0) = 0, \; -\frac{\mathrm{d}c}{\mathrm{d}x}(1) = Bi_m \left[c(1) - c_B \right]$$

the unknown solution is expanded in a series of known functions $\{b_i(x)\}$, with unknown coefficients $\{a_i\}$.

$$c(x) = \sum_{i=1}^{NT} a_i b_i(x)$$

The series (the trial solution) is inserted into the differential equation to obtain the residual:

$$\text{Residual} = \sum_{i=1}^{NT} a_i \frac{1}{x^{a-1}} \frac{\mathrm{d}}{\mathrm{d}x} \left(x^{a-1} \frac{\mathrm{d}b_i}{\mathrm{d}x} \right) - \varphi^2 R \left[\sum_{i=1}^{NT} a_i b_i(x) \right]$$

The residual is then made orthogonal to the set of basis functions.

$$\int_0^1 b_j(x) \left\{ \sum_{i=1}^{NT} a_i \frac{1}{x^{a-1}} \frac{\mathrm{d}}{\mathrm{d}x} \left(x^{a-1} \frac{\mathrm{d}b_i}{\mathrm{d}x} \right) - \varphi^2 R \left[\sum_{i=1}^{NT} a_i b_i(x) \right] \right\} x^{a-1} \mathrm{d}x = 0$$

$$j = 1, \ldots, NT$$

This process makes the method a Galerkin method. The basis for the orthogonality condition is that a function that is made orthogonal to each member of a complete set is then zero. The residual is being made orthogonal, and if the basis functions are complete, and an infinite number of them are used, then the residual is zero. Once the residual is zero the problem is solved. It is necessary also to allow for the boundary conditions. This is done by integrating the first term of Equation 26 by parts and then inserting the boundary conditions:

$$\begin{aligned} &\int_0^1 b_j(x) \frac{1}{x^{a-1}} \frac{\mathrm{d}}{\mathrm{d}x} \left(x^{a-1} \frac{\mathrm{d}b_i}{\mathrm{d}x} \right) x^{a-1} \mathrm{d}x = \\ &\int_0^1 \frac{\mathrm{d}}{\mathrm{d}x} \left[b_j(x) x^{a-1} \frac{\mathrm{d}b_i}{\mathrm{d}x} \right] \mathrm{d}x - \int_0^1 \frac{\mathrm{d}b_j}{\mathrm{d}x} \frac{\mathrm{d}b_i}{\mathrm{d}x} x^{a-1} \mathrm{d}x \\ &= \left[b_j(x) x^{a-1} \frac{\mathrm{d}b_i}{\mathrm{d}x} \right]_0^1 - \int_0^1 \frac{\mathrm{d}b_j}{\mathrm{d}x} \frac{\mathrm{d}b_i}{\mathrm{d}x} x^{a-1} \mathrm{d}x \\ &= -\int_0^1 \frac{\mathrm{d}b_j}{\mathrm{d}x} \frac{\mathrm{d}b_i}{\mathrm{d}x} x^{a-1} \mathrm{d}x - Bi_m b_j(1) \left[b_i(1) - c_B \right] \end{aligned} \tag{27}$$

Combining this with Equation 26 gives

$$\begin{aligned} &-\sum_{i=1}^{NT} \int_0^1 \frac{\mathrm{d}b_j}{\mathrm{d}x} \frac{\mathrm{d}b_i}{\mathrm{d}x} x^{a-1} \mathrm{d}x a_i \\ &- Bi_m b_j(1) \left[\sum_{i=1}^{NT} a_i b_i(1) - c_B \right] \\ &= \varphi^2 \int_0^1 b_j(x) \left[\sum_{i=1}^{NT} a_i b_i(x) \right] x^{a-1} \mathrm{d}x \\ &j = 1, \ldots, NT \end{aligned} \tag{28}$$

This equation defines the Galerkin method, and a solution that satisfies this equation (for all $j = 1, \ldots, \infty$) is called a weak solution. For an approximate solution the equation is written once for each member of the trial function, $j = 1, \ldots, NT$. If the boundary condition is

$$c(1) = c_B$$

then the boundary condition is used (instead of Eq. 28) for $j = NT$,

$$\sum_{i=1}^{NT} a_i b_i(1) = c_B$$

The Galerkin finite element method results when the Galerkin method is combined with a finite element trial function. Both linear and quadratic finite element approximations are described in Chapter 2. The trial functions $b_i(x)$ are then generally written as $N_i(x)$.

$$c(x) = \sum_{i=1}^{NT} c_i N_i(x)$$

Each $N_i(x)$ takes the value 1 at the point x_i and zero at all other grid points (Chap. 2). Thus c_i are the nodal values, $c(x_i) = c_i$. The first derivative must be transformed to the local coordinate system, $u = 0$ to 1 when x goes from x_i to $x_i + \Delta x$.

$$\frac{\mathrm{d}N_j}{\mathrm{d}x} = \frac{1}{\Delta x_e}\frac{\mathrm{d}N_J}{\mathrm{d}u},\ \mathrm{d}x = \Delta x_e \mathrm{d}u$$

in the e-th element. Then the Galerkin method is

$$\begin{aligned}
&-\sum\nolimits_e \frac{1}{\Delta x_e}\sum_{I=1}^{NP}\int_0^1 \frac{\mathrm{d}N_J}{\mathrm{d}u}\frac{\mathrm{d}N_I}{\mathrm{d}u}(x_e+u\Delta x_e)^{a-1}\mathrm{d}u c_I^e \\
&-Bi_m\sum\nolimits_e N_J(1)\left[\sum_{I=1}^{NP} c_I^e N_I(1) - c_1\right] \\
&= \varphi^2\sum\nolimits_e \Delta x_e \int_0^1 N_J(u)\, R\left[\sum_{I=1}^{NP} c_I^e N_I(u)\right] \\
&(x_e+u\Delta x_e)^{a-1}\mathrm{d}u
\end{aligned} \tag{29}$$

The element integrals are defined as

$$B_{JI}^e = -\frac{1}{\Delta x_e}\int_0^1 \frac{\mathrm{d}N_J}{\mathrm{d}u}\frac{\mathrm{d}N_I}{\mathrm{d}u}(x_e+u\Delta x_e)^{a-1}\mathrm{d}u,$$

$$F_J^e = \varphi^2\Delta x_e\int_0^1 N_J(u)\, R\left[\sum_{I=1}^{NP} c_I^e N_I(u)\right]$$
$$(x_e+u\Delta x_e)^{a-1}\mathrm{d}u$$

whereas the boundary element integrals are

$$BB_{JI}^e = -Bi_m N_J(1) N_I(1),$$

$$FF_J^e = -Bi_m N_J(1) c_1$$

Then the entire method can be written in the compact notation

$$\sum\nolimits_e B_{JI}^e c_I^e + \sum\nolimits_e BB_{JI}^e c_I^e = \sum\nolimits_e F_J^e + \sum\nolimits_e FF_J^e$$

The matrices for various terms are given in Table 10. This equation can also be written in the form

$$\boldsymbol{AAc} = \boldsymbol{f}$$

where the matrix $\boldsymbol{AA}$ is sparse. If linear elements are used the matrix is tridiagonal. If quadratic elements are used the matrix is pentadiagonal. Naturally the linear algebra is most efficiently carried out if the sparse structure is taken into account. Once the solution is found the solution at any point can be recovered from

$$c^e(u) = c_{I=1}^e(1-u) + c_{I=2}^e u$$

for linear elements

$$c^e(u) = c_{I=1}^e 2(u-1)\left(u-\tfrac{1}{2}\right)$$
$$+c_{I=2}^e 4u(1-u) + c_{I=3}^e 2u\left(u-\tfrac{1}{2}\right)$$

for quadratic elements

Table 10. Element matrices for Galerkin method

Linear shape functions	*Quadratic shape functions*
$N_1 = 1-u,\ N_2 = u,\ \frac{\mathrm{d}N_1}{\mathrm{d}u} = -1,\ \frac{\mathrm{d}N_2}{\mathrm{d}u} = 1$	$N_1 = 2(u-1)\left(u-\frac{1}{2}\right),\ N_2 = 4u(1-u),\ N_3 = 2u\left(u-\frac{1}{2}\right),$ $\frac{\mathrm{d}N_1}{\mathrm{d}u} = 4u-3,\ \frac{\mathrm{d}N_2}{\mathrm{d}u} = 4-8u,\ \frac{\mathrm{d}N_3}{\mathrm{d}u} = 4u-1$
$\int_0^1 \frac{\mathrm{d}N_J}{\mathrm{d}u}\frac{\mathrm{d}N_I}{\mathrm{d}u}\mathrm{d}u = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},\ \int_0^1 N_J\frac{\mathrm{d}N_I}{\mathrm{d}u}\mathrm{d}u = \begin{pmatrix} -\frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{pmatrix}$	$\int_0^1 \frac{\mathrm{d}N_J}{\mathrm{d}u}\frac{\mathrm{d}N_I}{\mathrm{d}u}\mathrm{d}u = \frac{1}{3}\begin{pmatrix} 7 & -8 & 1 \\ -8 & 16 & -8 \\ 1 & -8 & 7 \end{pmatrix},\ \int_0^1 N_J\frac{\mathrm{d}N_I}{\mathrm{d}u}\mathrm{d}u = \frac{1}{6}\begin{pmatrix} -3 & 4 & -1 \\ -4 & 0 & 4 \\ 1 & -4 & 3 \end{pmatrix}$
$\int_0^1 N_J N_I\,\mathrm{d}u = \begin{pmatrix} \frac{1}{3} & \frac{1}{6} \\ \frac{1}{6} & \frac{1}{3} \end{pmatrix},\ \int_0^1 N_J\,\mathrm{d}u = \begin{pmatrix} \frac{1}{2} \\ \frac{1}{2} \end{pmatrix},\ \int_0^1 N_J u\,\mathrm{d}u = \begin{pmatrix} \frac{1}{6} \\ \frac{1}{3} \end{pmatrix}$	$\int_0^1 N_J N_I\,\mathrm{d}u = \frac{1}{30}\begin{pmatrix} 4 & 2 & -1 \\ 2 & 16 & 2 \\ -1 & 2 & 4 \end{pmatrix},\ \int_0^1 N_J\,\mathrm{d}u = \frac{1}{6}\begin{pmatrix} 1 \\ 4 \\ 1 \end{pmatrix},\ \int_0^1 N_J u\,\mathrm{d}u = \frac{1}{6}\begin{pmatrix} 0 \\ 2 \\ 1 \end{pmatrix}$

Because the integrals in Equation 28 may be complicated, they are usually formed by using Gaussian quadrature. If *NG* Gauss points are used, a typical term would be

$$\int_0^1 N_J(u)\, R\left[\sum_{I=1}^{NP} c_I^e N_I(u)\right](x_e+u\Delta x_e)^{a-1}\mathrm{d}u$$
$$= \sum_{k=1}^{NG} W_k N_J(u_k)\, R\left[\sum_{I=1}^{NP} c_I^e N_I(u_k)\right]$$
$$(x_e+u_k\Delta x_e)^{a-1}$$

For an application of the finite element method in fluid mechanics, see → Fluid Mechanics, Chap. 5.2.

7.7. Cubic B-Splines

Cubic B-splines have cubic approximations within each element, but first and second derivatives continuous between elements. The functions are the same ones discussed in Chapter 2, and they can be used to solve differential equations, too. See Sincovec [92].

7.8. Adaptive Mesh Strategies

In many two-point boundary value problems, the difficulty in the problem is the formation of a boundary layer region, or a region in which the solution changes very dramatically. In such cases small mesh spacing should be used there, either with the finite difference method or the finite element method. If the region is known a priori, small mesh spacings can be assumed at the boundary layer. If the region is not known though, other techniques must be used. These techniques are known as adaptive mesh techniques. The general strategy is to estimate the error, which depends on the grid size and derivatives of the solution, and refine the mesh where the error is large.

The adaptive mesh strategy was employed by Ascher et al. [93] and by Russell and Christiansen [94]. For a second-order differential equation and cubic trial functions on finite elements, the error in the *i*-th element is given by

$$\|\text{Error}\|_i = c\Delta x_i^4 \|u^{(4)}\|_i$$

Because cubic elements do not have a nonzero fourth derivative, the third derivative in adjacent elements is used [3, p. 166]:

$$a_i = \frac{1}{\Delta x_i^3}\frac{\mathrm{d}^3 c^i}{\mathrm{d}u^3},\ a_{i+1} = \frac{1}{\Delta x_{i+1}^3}\frac{\mathrm{d}^3 c^{i+1}}{\mathrm{d}u^3}$$

$$\|u^{(4)}\|_i \approx \frac{1}{2}\left[\frac{a_i - a_{i-1}}{\frac{1}{2}(x_{i+1}-x_{i-1})} + \frac{a_{i+1}-a_i}{\frac{1}{2}(x_{i+2}-x_i)}\right]$$

Element sizes are then chosen so that the following error bounds are satisfied

$$C\Delta x_i^4 \|u^{(4)}\|_i \le \varepsilon \text{ for all } i$$

These features are built into the code COLSYS (http://www.netlib.org/ode/).

The error expected from a method one order higher and one order lower can also be defined. Then a decision about whether to increase or decrease the order of the method can be made by taking into account the relative work of the different orders. This provides a method of adjusting both the mesh spacing (Δx, sometimes called h) and the degree of polynomial (p). Such methods are called $h-p$ methods.

7.9. Comparison

What method should be used for any given problem? Obviously the error decreases with some power of Δx, and the power is higher for the higher order methods, which suggests that the error is less. For example, with linear elements the error is

$$y(\Delta x) = y_{\text{exact}} + c_2\Delta x^2$$

for small enough (and uniform) Δx. A computer code should be run for varying Δx to confirm this. For quadratic elements, the error is

$$y(\Delta x) = y_{\text{exact}} + c_3\Delta x^3$$

If orthogonal collocation on finite elements is used with cubic polynomials, then

$$y(\Delta x) = y_{\text{exact}} + c_4\Delta x^4$$

However, the global methods, not using finite elements, converge even faster [95], for example,

$$y(N) = y_{\text{exact}} + c_N\left(\frac{1}{NCOL}\right)^{NCOL}$$

Yet the workload of the methods is also different. These considerations are discussed in [3]. Here, only sweeping generalizations are given.

If the problem has a relatively smooth solution, then the orthogonal collocation method

is preferred. It gives a very accurate solution, and N can be quite small so the work is small. If the problem has a steep front in it, the finite difference method or finite element method is indicated, and adaptive mesh techniques should probably be employed. Consider the reaction – diffusion problem: as the Thiele modulus φ increases from a small value with no diffusion limitations to a large value with significant diffusion limitations, the solution changes as shown in Figure 28. The orthogonal collocation method is initially the method of choice. For intermediate values of φ, $N = 3 - 6$ must be used, but orthogonal collocation still works well (for η down to approximately 0.01). For large φ, use of the finite difference method, the finite element method, or an asymptotic expansion for large φ is better. The decision depends entirely on the type of solution that is obtained. For steep fronts the finite difference method and finite element method with adaptive mesh are indicated.

Figure 28. Concentration solution for different values of Thiele modulus

7.10. Singular Problems and Infinite Domains

If the solution being sought has a singularity, a good numerical solution may be hard to find. Sometimes even the location of the singularity may not be known [96, pp. 230 – 238]. One method of solving such problems is to refine the mesh near the singularity, by relying on the better approximation due to a smaller Δx. Another approach is to incorporate the singular trial function into the approximation. Thus, if the solution approaches $f(x)$ as x goes to zero, and $f(x)$ becomes infinite, an approximation may be taken as

$$y(x) = f(x) + \sum_{i=1}^{N} a_i y_i(x)$$

This function is substituted into the differential equation, which is solved for a_i. Essentially, a new differential equation is being solved for a new variable:

$$u(x) \equiv y(x) - f(x)$$

The differential equation is more complicated but has a better solution near the singularity (see [97, pp. 189 – 192], [98, p. 611]).

Sometimes the domain is infinite. Boundary layer flow past a flat plate is governed by the Blasius equation for stream function [99, p. 117].

$$2\frac{\mathrm{d}^3}{\mathrm{d}\eta^3} + f\frac{\mathrm{d}^2}{\mathrm{d}\eta^2} = 0$$

$$f = \frac{\mathrm{d}f}{\mathrm{d}\eta} = 0 \text{ at } \eta = 0$$

$$\frac{\mathrm{d}f}{\mathrm{d}\eta} = 1 \text{ at } \eta \to \infty$$

Because one boundary is at infinity using a mesh with a constant size is difficult! One approach is to transform the domain. For example, let

$$z = \mathrm{e}^{-\eta}$$

Then $\eta = 0$ becomes $z = 1$ and $\eta = \infty$ becomes $z = 0$. The derivatives are

$$\frac{\mathrm{d}z}{\mathrm{d}\eta} = -\mathrm{e}^{-\eta} = -z, \ \frac{\mathrm{d}^2 z}{\mathrm{d}\eta^2} = \mathrm{e}^{-\eta} = z$$

$$\frac{\mathrm{d}f}{\mathrm{d}\eta} = \frac{\mathrm{d}f}{\mathrm{d}z}\frac{\mathrm{d}z}{\mathrm{d}\eta} = -z\frac{\mathrm{d}f}{\mathrm{d}z}$$

$$\frac{\mathrm{d}^2 f}{\mathrm{d}\eta^2} = \frac{\mathrm{d}^2 f}{\mathrm{d}z^2}\left(\frac{\mathrm{d}z}{\mathrm{d}\eta}\right)^2 + \frac{\mathrm{d}f}{\mathrm{d}z}\frac{\mathrm{d}^2 z}{\mathrm{d}\eta^2} = z^2\frac{\mathrm{d}^2 f}{\mathrm{d}z^2} + z\frac{\mathrm{d}f}{\mathrm{d}z}$$

The Blasius equation becomes

$$2\left[-z^3\frac{\mathrm{d}^3 f}{\mathrm{d}z^3} - 3z^2\frac{\mathrm{d}^2 f}{\mathrm{d}z^2} - z\frac{\mathrm{d}f}{\mathrm{d}z}\right]$$

$$+ f\left[z^2\frac{\mathrm{d}^2}{\mathrm{d}z^2} + z\frac{\mathrm{d}f}{\mathrm{d}z}\right] = 0 \qquad \text{for } 0 \le z \le 1.$$

The differential equation now has variable coefficients, but these are no more difficult to handle than the original nonlinearities.

Another approach is to use a variable mesh, perhaps with the same transformation. For example, use $z = e^{-\eta}$ and a constant mesh size in z. Then with 101 points distributed uniformly from $z = 0$ to $z = 1$, the following are the nodal points:

$$z = 0.,0.01,0.02,\ldots,0.99,1.0$$

$$\eta = \infty,4.605,3.912,\ldots,0.010,0$$

$$\Delta\eta = \infty,0.639,\ldots,0.01$$

Still another approach is to solve on a finite mesh in which the last point is far enough away that its location does not influence the solution. A location that is far enough away must be found by trial and error.

8. Partial Differential Equations

Partial differential equations are differential equations in which the dependent variable is a function of two or more independent variables. These can be time and one space dimension, or time and two or more space dimensions, or two or more space dimensions alone. Problems involving time are generally either hyperbolic or parabolic, whereas those involving spatial dimensions only are often elliptic. Because the methods applied to each type of equation are very different, the equation must first be classified as to its type. Then the special methods applicable to each type of equation are described. For a discussion of all methods, see [100 – 103]; for a discussion oriented more toward chemical engineering applications, see [104]. Examples of hyperbolic and parabolic equations include chemical reactors with radial dispersion, pressure-swing adsorption, dispersion of an effluent, and boundary value problems with transient terms added (heat transfer, mass transfer, chemical reaction). Examples of elliptic problems include heat transfer and mass transfer in two and three spatial dimensions and steady fluid flow.

8.1. Classification of Equations

A set of differential equations may be hyperbolic, elliptic, or parabolic, or it may be of mixed type. The type may change for different parameters or in different regions of the flow. This can happen in the case of nonlinear problems; an example is a compressible flow problem with both subsonic and supersonic regions. *Characteristic curves* are curves along which a discontinuity can propagate. For a given set of equations, it is necessary to determine if characteristics exist or not, because that determines whether the equations are hyperbolic, elliptic, or parabolic.

Linear Problems For linear problems, the theory summarized by Joseph et al. [105] can be used.

$$\frac{\partial}{\partial t},\frac{\partial}{\partial x_i},\ldots,\frac{\partial}{\partial x_n}$$

is replaced with the Fourier variables

$$i\xi_0,i\xi_1,\ldots,i\xi_n$$

If the m-th order differential equation is

$$P = \sum\nolimits_{|\alpha|=m} a_\alpha \partial^\alpha + \sum\nolimits_{|\alpha|<m} b_\alpha \partial^\alpha$$

where

$$\alpha = (\alpha_0,\alpha_1,\ldots,\alpha_n)\,,\ |\alpha| = \sum_{i=0}^{n} \alpha_i$$

$$\partial^\alpha = \frac{\partial^{|\alpha|}}{\partial t^{\alpha_0}\partial x_1^{\alpha_1}\ldots\partial x_n^{\alpha_n}}$$

the characteristic equation for P is defined as

$$\begin{aligned} &\textstyle\sum_{|\alpha|=m} a_\alpha \sigma^\alpha = 0,\ \sigma = (\sigma_0,\sigma_1,\ldots,\sigma_n) \\ &\sigma^\alpha = \sigma_0^{\alpha_0}\sigma_1^{\alpha_1}\ldots\sigma_n^{\alpha_n} \end{aligned} \tag{30}$$

where σ represents coordinates. Thus only the highest derivatives are used to determine the type. The surface is defined by this equation plus a normalization condition:

$$\sum_{k=0}^{n} \sigma_k^2 = 1$$

The shape of the surface defined by Equation 30 is also related to the type: elliptic equations give rise to ellipses; parabolic equations give rise to parabolas; and hyperbolic equations give rise to hyperbolas.

$$\frac{\sigma_1^2}{a^2} + \frac{\sigma_2^2}{b^2} = 1,\ \text{Ellipse}$$

$$\sigma_0 = a\sigma_1^2,\ \text{Parabola}$$

$$\sigma_0^2 - a\sigma_1^2 = 0,\ \text{Hyperbola}$$

If Equation 30 has no nontrivial real zeroes then the equation is called elliptic. If all the roots are

real and distinct (excluding zero) then the operator is hyperbolic.

This formalism is applied to three basic types of equations. First consider the equation arising from steady diffusion in two dimensions:

$$\frac{\partial^2 c}{\partial x^2}+\frac{\partial^2 c}{\partial y^2}=0$$

This gives

$$-\xi_1^2-\xi_2^2=-\left(\xi_2^1+\xi_2^2\right)=0$$

Thus,

$$\sigma_1^2+\sigma_2^2=1 \text{ (normalization)}$$

$$\sigma_1^2+\sigma_2^2=0 \text{ (equation)}$$

These cannot both be satisfied so the problem is elliptic. When the equation is

$$\frac{\partial^2 u}{\partial t^2}-\frac{\partial^2 u}{\partial x^2}=0$$

then

$$-\xi_0^2+\xi_1^2=0$$

Now real ξ_0 can be solved and the equation is hyperbolic

$$\sigma_0^2+\sigma_1^2=1 \text{ (normalization)}$$

$$-\sigma_0^2+\sigma_1^2=0 \text{ (equation)}$$

When the equation is

$$\frac{\partial c}{\partial t}=D\left(\frac{\partial^2 c}{\partial x^2}+\frac{\partial^2 c}{\partial y^2}\right)$$

then

$$\sigma_0^2+\sigma_1^2+\sigma_2^2=1 \text{ (normalization)}$$

$$\sigma_1^2+\sigma_2^2=0 \text{ (equation)}$$

thus we get

$$\sigma_0^2=1 \text{ (for normalization)}$$

and the characteristic surfaces are hyperplanes with t = constant. This is a parabolic case.

Consider next the telegrapher's equation:

$$\frac{\partial T}{\partial t}+\beta\frac{\partial^2 T}{\partial t^2}=\frac{\partial^2 T}{\partial x^2}$$

Replacing the derivatives with the Fourier variables gives

$$i\xi_0-\beta\xi_0^2+\xi_1^2=0$$

The equation is thus second order and the type is determined by

$$-\beta\sigma_0^2+\sigma_1^2=0$$

The normalization condition

$$\sigma_0^2+\sigma_1^2=1$$

is required. Combining these gives

$$1-(1+\beta)\,\sigma_0^2=0$$

The roots are real and the equation is hyperbolic. When $\beta = 0$

$$\xi_1^2=0$$

and the equation is parabolic.

First-order quasi-linear problems are written in the form

$$\sum_{l=0}^{n}\boldsymbol{A}_1\frac{\partial \boldsymbol{u}}{\partial x_1}=\boldsymbol{f},\ \boldsymbol{x}=(t,x_1\ldots,x_n) \qquad (31)$$
$$\boldsymbol{u}=(u_1,u_2,\ldots,u_k)$$

The matrix entries $\boldsymbol{A}_1$ is a $k\times k$ matrix whose entries depend on $\boldsymbol{u}$ but not on derivatives of $\boldsymbol{u}$. Equation 31 is hyperbolic if

$$\mathrm{A}=\mathrm{A}_\mu$$

is nonsingular and for any choice of real λ_1, l = 0, . . . , n, $l \neq \mu$ the roots α_k of

$$\det\left(\alpha\boldsymbol{A}-\sum_{\substack{l=0\\ l\neq\mu}}^{n}\lambda_1\boldsymbol{A}_1\right)=0$$

are real. If the roots are complex the equation is elliptic; if some roots are real and some are complex the equation is of mixed type.

Apply these ideas to the *advection equation*

$$\frac{\partial u}{\partial t}+F(u)\frac{\partial u}{\partial x}=0$$

Thus,

$$\det(\alpha\boldsymbol{A}_0-\lambda_1\boldsymbol{A}_1)=0 \text{ or } \det(\alpha\boldsymbol{A}_1-\lambda_0\boldsymbol{A}_0)=0$$

In this case,

$$n=1,\ \boldsymbol{A}_0=1,\ \boldsymbol{A}_1=F(u)$$

Using the first of the above equations gives

$$\det(\alpha-\lambda_1F(u))=0, \text{or } \alpha=\lambda_1F(u)$$

Thus, the roots are real and the equation is hyperbolic.

The final example is the heat conduction problem written as

$$\varrho C_p \frac{\partial T}{\partial t} = -\frac{\partial q}{\partial x},\ q = -k\frac{\partial T}{\partial x}$$

In this formulation the constitutive equation for heat flux is separated out; the resulting set of equations is first order and written as

$$\varrho C_p \tfrac{\partial T}{\partial t} + \tfrac{\partial q}{\partial x} = 0$$

$$k\tfrac{\partial T}{\partial x} = -q$$

In matrix notation this is

$$\begin{bmatrix} \varrho C_p & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \frac{\partial T}{\partial t} \\ \frac{\partial q}{\partial t} \end{bmatrix} + \begin{bmatrix} 0 & 1 \\ k & 0 \end{bmatrix} \begin{bmatrix} \frac{\partial T}{\partial x} \\ \frac{\partial q}{\partial t} \end{bmatrix} = \begin{bmatrix} 0 \\ -q \end{bmatrix}$$

This compares with

$$\boldsymbol{A}_0 \frac{\partial \boldsymbol{u}}{\partial x_0} + \boldsymbol{A}_1 \frac{\partial \boldsymbol{u}}{\partial x_1} = \boldsymbol{f}$$

In this case $\boldsymbol{A}_0$ is singular whereas $\boldsymbol{A}_1$ is nonsingular. Thus,

$$\det\left(\alpha \boldsymbol{A}_1 - \lambda_0 \boldsymbol{A}_0\right) = 0$$

is considered for any real λ_0. This gives

$$\begin{vmatrix} -\varrho C_p \lambda_0 & \alpha \\ k\alpha & 0 \end{vmatrix} = 0$$

or

$$\alpha^2 k = 0$$

Thus the α is real, but zero, and the equation is parabolic.

8.2. Hyperbolic Equations

The most common situation yielding hyperbolic equations involves unsteady phenomena with convection. A prototype equation is

$$\frac{\partial c}{\partial t} + \frac{\partial F(c)}{\partial x} = 0$$

Depending on the interpretation of c and $F(c)$, this can represent accumulation of mass and convection. With $F(c) = u\,c$, where u is the velocity, the equation represents a mass balance on concentration. If diffusive phenomenon are important, the equation is changed to

$$\frac{\partial c}{\partial t} + \frac{\partial F(c)}{\partial x} = D\frac{\partial^2 c}{\partial x^2} \tag{32}$$

where D is a diffusion coefficient. Special cases are the *convective diffusive equation*

$$\frac{\partial c}{\partial t} + u\frac{\partial c}{\partial x} = D\frac{\partial^2 c}{\partial x^2} \tag{33}$$

and *Burgers viscosity equation*

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = \nu\frac{\partial^2 u}{\partial x^2} \tag{34}$$

where u is the velocity and ν is the kinematic viscosity. This is a prototype equation for the Navier – Stokes equations (→ Fluid Mechanics). For *adsorption phenomena* [106, p. 202],

$$\varphi\frac{\partial c}{\partial t} + \varphi u\frac{\partial c}{\partial x} + (1-\varphi)\frac{\mathrm{d}f}{\mathrm{d}c}\frac{\partial c}{\partial t} = 0 \tag{35}$$

where φ is the void fraction and $f(c)$ gives the equilibrium relation between the concentrations in the fluid and in the solid phase. In these examples, if the diffusion coefficient D or the kinematic viscosity ν is zero, the equations are hyperbolic. If D and ν are small, the phenomenon may be essentially hyperbolic even though the equations are parabolic. Thus the numerical methods for hyperbolic equations may be useful even for parabolic equations.

Equations for several methods are given here, as taken from [107]. If the convective term is treated with a centered difference expression the solution exhibits oscillations from node to node, and these vanish only if a very fine grid is used. The simplest way to avoid the oscillations with a hyperbolic equation is to use upstream derivatives. If the flow is from left to right, this would give the following for Equations (40):

$$\frac{\mathrm{d}c_i}{\mathrm{d}t} + \frac{F(c_i) - F(c_{i-1})}{\Delta x} = D\frac{c_{i+1} - 2c_i + c_{i-1}}{\Delta x^2}$$

for Equation 34:

$$\frac{\mathrm{d}u_i}{\mathrm{d}t} + u_i\frac{u_i - u_{i-1}}{\Delta x} = \nu\frac{u_{i+1} - 2u_i + u_{i-1}}{\Delta x^2}$$

and for Equation 35:

$$\varphi\frac{\mathrm{d}c_i}{\mathrm{d}t} + \varphi u_i\frac{c_i - c_{i-1}}{\Delta x} + (1-\varphi)\frac{\mathrm{d}f}{\mathrm{d}c}\Big|_i\frac{\mathrm{d}c_i}{\mathrm{d}t} = 0$$

If the flow were from right to left, then the formula would be

$$\frac{\mathrm{d}c_i}{\mathrm{d}t} + \frac{F(c_{i+1}) - F(c_i)}{\Delta x} = D\frac{c_{i+1} - 2c_i + c_{i-1}}{\Delta x^2}$$

If the flow could be in either direction, a local determination must be made at each node i and the appropriate formula used. The effect of using upstream derivatives is to add artificial or numerical diffusion to the model. This can be

ascertained by taking the finite difference form of the convective diffusion equation

$$\frac{\mathrm{d}c_i}{\mathrm{d}t}+u\frac{c_i-c_{i-1}}{\Delta x}=D\frac{c_{i+1}-2c_i+c_{i-1}}{\Delta x^2}$$

and rearranging

$$\frac{\mathrm{d}c_i}{\mathrm{d}t}+u\frac{c_{i+1}-c_{i-1}}{2\Delta x}$$

$$=\left(D+\frac{u\Delta x}{2}\right)\frac{c_{i+1}-2c_i+c_{i-1}}{\Delta x^2}$$

Thus the diffusion coefficient has been changed from

$$D \text{ to } D+\frac{u\Delta x}{2}$$

Expressed in terms of the cell Peclet number, $Pe_\Delta = u\Delta x/D$, this is D is changed to $D[1+Pe_\Delta/2]$

The cell Peclet number should always be calculated as a guide to the calculations. Using a large cell Peclet number and upstream derivatives leads to excessive (and artificial) smoothing of the solution profiles.

Another method often used for hyperbolic equations is the *MacCormack method*. This method has two steps; it is written here for Equation 33.

$$c_i^{*n+1}=c_i^n-\frac{u\Delta t}{\Delta x}\left(c_{i+1}^n-c_i^n\right)$$

$$+\frac{\Delta t D}{\Delta x^2}\left(c_{i+1}^n-2c_i^n+c_{i-1}^n\right)$$

$$c_i^{n+1}=\frac{1}{2}\left(c_i^n+c_i^{*n+1}\right)-\frac{u\Delta t}{2\Delta x}\left(c_i^{*n+1}-c_{i-1}^{*n+1}\right)$$

$$+\frac{\Delta t D}{2\Delta x^2}\left(c_{i+1}^{*n+1}-2c_i^{*n+1}+c_{i-1}^{*n+1}\right)$$

The concentration profile is steeper for the MacCormack method than for the upstream derivatives, but oscillations can still be present. The flux-corrected transport method can be added to the MacCormack method. A solution is obtained both with the upstream algorithm and the MacCormack method; then they are combined to add just enough diffusion to eliminate the oscillations without smoothing the solution too much. The algorithm is complicated and lengthy but well worth the effort [107 – 109].

If finite element methods are used, an explicit Taylor – Galerkin method is appropriate. For the convective diffusion equation the method is

$$\frac{1}{6}\left(c_{i+1}^{n+1}-c_{i+1}^n\right)+\frac{2}{3}\left(c_i^{n+1}-c_i^n\right)+\frac{1}{6}\left(c_{i-1}^{n+1}-c_{i-1}^n\right)$$

$$=-\frac{u\Delta t}{2\Delta x}\left(c_{i+1}^n-c_{i-1}^n\right)+\left(\frac{\Delta t D}{\Delta x^2}+\frac{u^2\Delta t^2}{2\Delta x^2}\right)\left(c_{i+1}^n\right.$$

$$\left.-2c_i^n+c_{i-1}^n\right)$$

Leaving out the $u^2\ \Delta t^2$ terms gives the Galerkin method. Replacing the left-hand side with

$$c_i^{n+1}-c_i^n$$

gives the Taylor finite difference method, and dropping the $u^2\ \Delta t^2$ terms in that gives the centered finite difference method. This method might require a small time step if reaction phenomena are important. Then the implicit Galerkin method (without the Taylor terms) is appropriate

A stability diagram for the explicit methods applied to the convective diffusion equation is shown in Figure 29. Notice that all the methods require

$$Co=\frac{u\Delta t}{\Delta x}\leq 1$$

where *Co* is the Courant number. How much *Co* should be less than one depends on the method and on $r = D\ \Delta t/\Delta x^2$, as given in Figure 29. The MacCormack method with flux correction requires a smaller time step than the MacCormack method alone (curve a), and the implicit Galerkin method (curve e) is stable for all values of *Co* and *r* shown in Figure 29 (as well as even larger values).

Figure 29. Stability diagram for convective diffusion equation (stable below curve)
a) MacCormack; b) Centered finite difference; c) Taylor finite difference; d) Upstream; e) Galerkin; f) Taylor – Galerkin

Each of these methods tries to avoid oscillations that would disappear if the mesh were

fine enough. For the steady convective diffusion equation these oscillations do not occur provided

$$\frac{u\Delta x}{2D} = \frac{Pe_{\Delta}}{2} <= 1 \tag{36}$$

For large u, Δx must be small to meet this condition. An alternative is to use a small Δx in regions where the solution changes drastically. Because these regions change in time, the elements or grid points must move. The criteria to move the grid points can be quite complicated, and typical methods are reviewed in [107]. The criteria include moving the mesh in a known way (when the movement is known a priori), moving the mesh to keep some property (e.g., first- or second-derivative measures) uniform over the domain, using a Galerkin or weighted residual criterion to move the mesh, and Euler – Lagrange methods which move part of the solution exactly by convection and then add on some diffusion after that.

The final illustration is for adsorption in a packed bed, or chromatography. Equation 35 can be solved when the adsorption phenomenon is governed by a Langmuir isotherm.

$$f(c) = \frac{\alpha c}{1+Kc}$$

Similar numerical considerations apply and similar methods are available [110 – 112].

8.3. Parabolic Equations in One Dimension

In this section several methods are applied to parabolic equations in one dimension: separation of variables, combination of variables, finite difference method, finite element method, and the orthogonal collocation method. Separation of variables is successful for linear problems, whereas the other methods work for linear or nonlinear problems. The finite difference, the finite element, and the orthogonal collocation methods are numerical, whereas the separation or combination of variables can lead to analytical solutions.

Analytical Solutions. Consider the diffusion equation

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2}$$

with boundary and initial conditions

$$c(x,0) = 0$$

$$c(0,t) = 1,\ c(L,t) = 0$$

A solution of the form

$$c(x,t) = T(t)\,X(x)$$

is attempted and substituted into the equation, with the terms separated to give

$$\frac{1}{DT}\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{1}{X}\frac{\mathrm{d}^2X}{\mathrm{d}x^2}$$

One side of this equation is a function of x alone, whereas the other side is a function of t alone. Thus, both sides must be a constant. Otherwise, if x is changed one side changes, but the other cannot because it depends on t. Call the constant $-\lambda$ and write the separate equations

$$\frac{\mathrm{d}T}{\mathrm{d}t} - \lambda DT,\ \frac{\mathrm{d}^2X}{\mathrm{d}x^2} - \lambda X$$

The first equation is solved easily

$$T(t) = T(0)\,\mathrm{e}^{-\lambda Dt}$$

and the second equation is written in the form

$$\frac{\mathrm{d}^2X}{\mathrm{d}x^2} + \lambda X = 0$$

Next consider the boundary conditions. If they are written as

$$c(L,t) = 1 = T(t)\,X(L)$$

$$c(0,t) = 0 = T(t)\,X(0)$$

the boundary conditions are difficult to satisfy because they are not homogeneous, i.e. with a zero right-hand side. Thus, the problem must be transformed to make the boundary conditions homogeneous. The solution is written as the sum of two functions, one of which satisfies the nonhomogeneous boundary conditions, whereas the other satisfies the homogeneous boundary conditions.

$$c(x,t) = f(x) + u(x,t)$$

$$u(0,t) = 0$$

$$u(L,t) = 0$$

Thus, $f(0) = 1$ and $f(L) = 0$ are necessary. Now the combined function satisfies the boundary conditions. In this case the function $f(x)$ can be taken as

$$f(x) = L - x$$

The equation for u is found by substituting for c in the original equation and noting that the $f(x)$ drops out for this case; it need not disappear in the general case:

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2}$$

The boundary conditions for u are

$$u(0,t) = 0$$

$$u(L,t) = 0$$

The initial conditions for u are found from the initial condition

$$u(x,0) = c(x,0) - f(x) = \frac{x}{L} - 1$$

Separation of variables is now applied to this equation by writing

$$u(x,t) = T(t)\,X(x)$$

The same equation for $T(t)$ and $X(x)$ is obtained, but with $X(0) = X(L) = 0$.

$$\frac{d^2X}{dx^2} + \lambda X = 0$$

$$X(0) = X(L) = 0$$

Next $X(x)$ is solved for. The equation is an eigenvalue problem. The general solution is obtained by using e^{mx} and finding that $m^2 + \lambda = 0$; thus $m = \pm i\sqrt{\lambda}$. The exponential term

$$e^{\pm i\sqrt{\lambda}x}$$

is written in terms of sines and cosines, so that the general solution is

$$X = B\cos\sqrt{\lambda}x + E\sin\sqrt{\lambda}x$$

The boundary conditions are

$$X(L) = B\cos\sqrt{\lambda}L + E\sin\sqrt{\lambda}L = 0$$

$$X(0) = B = 0$$

If $B = 0$, then $E \neq 0$ is required to have any solution at all. Thus, λ must satisfy

$$\sin\sqrt{\lambda}L = 0$$

This is true for certain values of λ, called eigenvalues or characteristic values. Here, they are

$$\lambda_n = n^2\pi^2/L^2$$

Each eigenvalue has a corresponding eigenfunction

$$X_n(x) = E\sin n\pi x/L$$

The composite solution is then

$$X_n(x)\,T_n(t) = E\,A\sin\frac{n\pi x}{L}\,e^{-\lambda_n Dt}$$

This function satisfies the boundary conditions and differential equation but not the initial condition. To make the function satisfy the initial condition, several of these solutions are added up, each with a different eigenfunction, and $E\,A$ is replaced by A_n.

$$u(x,t) = \sum_{n=1}^{\infty} A_n \sin\frac{n\pi x}{L}\,e^{-n^2\pi^2 Dt/L^2}$$

The constants A_n are chosen by making $u(x, t)$ satisfy the initial condition.

$$u(x,0) = \sum_{n=1}^{\infty} A_n \sin\frac{n\pi x}{L} = \frac{x}{L} - 1$$

The residual $R(x)$ is defined as the error in the initial condition:

$$R(x) = \frac{x}{L} - 1 - \sum_{n=1}^{\infty} A_n \sin\frac{n\pi x}{L}$$

Next, the Galerkin method is applied, and the residual is made orthogonal to a complete set of functions, which are the eigenfunctions.

$$\int_0^L \left(\frac{x}{L} - 1\right)\sin\frac{m\pi x}{L}\,dx$$

$$= \sum_{n=1}^{\infty} A_n \int_0^L \sin\frac{m\pi x}{L}\sin\frac{n\pi x}{L}\,dx = \frac{A_m}{2}$$

The Galerkin criterion for finding A_n is the same as the least-squares criterion [3, p. 183]. The solution is then

$$c(x,t) = 1 - \frac{x}{L} + \sum_{n=1}^{\infty} A_n \sin\frac{n\pi x}{L}\,e^{-n^2\pi^2 Dt/L^2}$$

This is an "exact" solution to the linear problem. It can be evaluated to any desired accuracy by taking more and more terms, but if a finite number of terms are used, some error always occurs. For large times a single term is adequate, whereas for small times many terms are needed. For small times the Laplace transform method is also useful, because it leads to solutions that converge with fewer terms. For small times, the method of combination of variables may be used

as well. For nonlinear problems, the method of separation of variables fails and one of the other methods must be used.

The method of combination of variables is useful, particularly when the problem is posed in a semi-infinite domain. Here, only one example is provided; more detail is given in [3, 113, 114]. The method is applied here to the nonlinear problem

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left[D(c)\frac{\partial c}{\partial x}\right] = D(c)\frac{\partial^2 c}{\partial x^2} + \frac{\mathrm{d}\,D(c)}{\mathrm{d}c}\left(\frac{\partial c}{\partial x}\right)^2$$

with boundary and initial conditions

$$c(x,0) = 0$$

$$c(0,t) = 1,\ c(\infty,t) = 0$$

The transformation combines two variables into one

$$c(x,t) = f(\eta) \text{ where } \eta = \frac{x}{\sqrt{4D_0 t}}$$

The use of the 4 and D_0 makes the analysis below simpler. The equation for c (x, t) is transformed into an equation for f (η)

$$\frac{\partial c}{\partial t} = \frac{\mathrm{d}f}{\mathrm{d}\eta}\frac{\partial \eta}{\partial t},\ \frac{\partial c}{\partial x} = \frac{\mathrm{d}f}{\mathrm{d}\eta}\frac{\partial \eta}{\partial x}$$

$$\frac{\partial^2 c}{\partial x^2} = \frac{\mathrm{d}^2 f}{\mathrm{d}\eta^2}\left(\frac{\partial \eta}{\partial x}\right)^2 + \frac{\mathrm{d}f}{\mathrm{d}\eta}\frac{\partial^2 \eta}{\partial x^2}$$

$$\frac{\partial \eta}{\partial t} = -\frac{x/2}{\sqrt{4D_0 t^3}},\ \frac{\partial \eta}{\partial x} = \frac{1}{\sqrt{4D_0 t}},\ \frac{\partial^2 \eta}{\partial x^2} = 0$$

The result is

$$\frac{\mathrm{d}}{\mathrm{d}\eta}\left[K(c)\frac{\mathrm{d}f}{\mathrm{d}\eta}\right] + 2\eta\frac{\mathrm{d}f}{\mathrm{d}\eta} = 0$$

$$K(\mathrm{c}) = D(c)/D_0$$

The boundary conditions must also combine. In this case the variable η is infinite when either x is infinite or t is zero. Note that the boundary conditions on c (x, t) are both zero at those points. Thus, the boundary conditions can be combined to give

$$f(\infty) = 0$$

The other boundary condition is for $x = 0$ or $\eta = 0$,

$$f(0) = 1$$

Thus, an ordinary differential equation must be solved rather than a partial differential equation. When the diffusivity is constant the solution is the well-known complementary error function:

$$c(x,t) = 1 - \mathrm{erf}\,\eta = \mathrm{erfc}\,\eta$$

$$\mathrm{erf}\,\eta = \frac{\int_0^{\eta} \mathrm{e}^{-\xi^2}\mathrm{d}\xi}{\int_0^{\infty} \mathrm{e}^{-\xi^2}\mathrm{d}\xi}$$

This is a tabulated function [23].

Numerical Methods. Numerical methods are applicable to both linear and nonlinear problems on finite and semi-infinite domains. The *finite difference method* is applied by using the method of lines [115]. In this method the same equations are used for the spatial variations of the function, but the function at a grid point can vary with time. Thus the linear diffusion problem is written as

$$\frac{\mathrm{d}c_i}{\mathrm{d}t} = D\frac{c_{i+1} - 2c_i + c_{i-1}}{\Delta x^2} \tag{37}$$

This can be written in the general form

$$\frac{\mathrm{d}\boldsymbol{c}}{\mathrm{d}t} = \boldsymbol{A}\boldsymbol{A}c$$

This set of ordinary differential equations can be solved by using any of the standard methods. The stability of explicit schemes is deduced from the theory presented in Chapter 6. The equations are written as

$$\frac{\mathrm{d}c_i}{\mathrm{d}t} = D\frac{c_{i+1} - 2c_i + c_{i-1}}{\Delta x^2} = \frac{D}{\Delta x^2}\sum_{j=1}^{n+1} B_{ij}c_j$$

where the matrix $\boldsymbol{B}$ is tridiagonal. The stability of the integration of these equations is governed by the largest eigenvalue of $\boldsymbol{B}$. If Euler's method is used for integration,

$$\Delta t\frac{D}{\Delta x^2} \le \frac{2}{|\lambda|_{\max}}$$

The largest eigenvalue of $\boldsymbol{B}$ is bounded by the Gerschgorin theorem [14, p. 135].

$$|\lambda|_{\max} \le \max_{2<j<n}\sum_{i=2}^{n}|B_{ji}| = 4$$

This gives the well-known stability limit

$$\Delta t\frac{D}{\Delta x^2} \le \frac{1}{2}$$

If other methods are used to integrate in time, then the stability limit changes according to the method. It is interesting to note that the eigenvalues of Equation 37 range from $D\,\pi^2/L^2$ (smallest) to $4\,D/\Delta x^2$ (largest), depending on

the boundary conditions. Thus the problem becomes stiff as Δx approaches zero [3, p. 263].

Implicit methods can also be used. Write a finite difference form for the time derivative and average the right-hand sides, evaluated at the old and new times:

$$\frac{c_i^{n+1}-c_i^n}{\Delta t} = D\,(1-\theta)\,\frac{c_{i+1}^n-2c_i^n+c_{i-1}^n}{\Delta x^2}$$
$$+D\theta\frac{c_{i+1}^{n+1}-2c_i^{n+1}+c_{i-1}^{n+1}}{\Delta x^2}$$

Now the equations are of the form

$$-\frac{D\Delta t\theta}{\Delta x^2}c_{i+1}^{n+1}+\left[1+2\frac{D\Delta t\theta}{\Delta x^2}\right]c_i^{n+1}-\frac{D\Delta t\theta}{\Delta x^2}c_{i-1}^{n+1}$$
$$=c_i^n+\frac{D\Delta t(1-\theta)}{\Delta x^2}\left(c_{i+1}^n-2c_i^n+c_{i-1}^n\right)$$

and require solving a set of simultaneous equations, which have a tridiagonal structure. Using $\theta = 0$ gives the Euler method (as above); $\theta = 0.5$ gives the Crank – Nicolson method; $\theta = 1$ gives the backward Euler method. The stability limit is given by

$$\frac{D\Delta t}{\Delta x^2}\leq\frac{0.5}{1-2\theta}$$

whereas the oscillation limit is given by

$$\frac{D\Delta t}{\Delta x^2}\leq\frac{0.25}{1-\theta}$$

If a time step is chosen between the oscillation limit and stability limit, the solution will oscillate around the exact solution, but the oscillations remain bounded. For further discussion, see [3, p. 218].

Finite volume methods are utilized extensively in computational fluid dynamics. In this method, a mass balance is made over a cell accounting for the change in what is in the cell and the flow in and out. Figure 30 illustrates the geometry of the *i*-th cell. A mass balance made on this cell (with area A perpendicular to the paper) is

$$A\Delta x(c_i^{n+1}-c_i^n) = \Delta tA(J_{j-1/2}-J_{i+1/2})$$

where J is the flux due to convection and diffusion, positive in the $+x$ direction.

$$J = uc-D\frac{\partial c}{\partial x},\, J_{i-1/2} = u_{i-1/2}c_{i-1/2}-D\frac{c_i-c_{i-1/2}}{\Delta x}$$

The concentration at the edge of the cell is taken as

$$c_{i-1/2} = \frac{1}{2}(c_i+c_{i-1})$$

Rearrangement for the case when the velocity u is the same for all nodes gives

$$\frac{c_i^{n+1}-c_i^n}{\Delta t}+\frac{u(c_{i+1}-c_{i-1})}{2\Delta x} = \frac{D}{\Delta x^2}(c_{i+1}-2c_i+c_{i-1})$$

This is the same equation as obtained using the finite difference method. This is not always true, and the finite volume equations are easy to derive. In two- and three-dimensions, the mesh need not be rectangular, as long as it is possible to compute the velocity normal to an edge of the cell. The finite volume method is useful for applications involving filling, such as injection molding, when only part of the cell is filled with fluid. Such applications do involve some approximations, since the interface is not tracked precisely, but they are useful engineering approximations.

Figure 30.

The *finite element method* is handled in a similar fashion, as an extension of two-point boundary value problems by letting the solution at the nodes depend on time. For the diffusion equation the finite element method gives

$$\sum\nolimits_e\sum\nolimits_I C_{JI}^e\frac{\mathrm{d}c_I^e}{\mathrm{d}t} = \sum\nolimits_e\sum\nolimits_I B_{JI}^e\,c_I^e$$

with the mass matrix defined by

$$C_{JI}^e = \Delta x_e\int_0^1 N_J\,(u)\,N_I\,(u)\,\mathrm{d}u$$

This set of equations can be written in matrix form

$$\boldsymbol{CC}\frac{\mathrm{d}c}{\mathrm{d}t} = \boldsymbol{AA}c$$

Now the matrix $\boldsymbol{C}\,\boldsymbol{C}$ is not diagonal, so that a set of equations must be solved for each time step, even when the right-hand side is evaluated explicitly. This is not as time-consuming as it seems, however. The explicit scheme is written as

$$CC_{ji}\frac{c_i^{n+1}-c_i^n}{\Delta t}=AA_{ji}c_i^n$$

and rearranged to give

$$CC_{ji}\left(c_i^{n+1}-c_i^n\right)=\Delta tAA_{ji}c_i^n \text{ or}$$

$$\boldsymbol{CC}\left(\boldsymbol{c}^{n+1}-\boldsymbol{c}^n\right)=\Delta t\boldsymbol{AAc}$$

This is solved with an $L\,U$ decomposition (see Section 1.1) that retains the structure of the mass matrix $\boldsymbol{C}\,\boldsymbol{C}$. Thus,

$$\boldsymbol{CC}=\boldsymbol{LU}$$

At each step, calculate

$$\boldsymbol{c}^{n+1}-\boldsymbol{c}^n=\Delta t\boldsymbol{U}^{-1}\boldsymbol{L}^{-1}\boldsymbol{AAc}^n$$

This is quick and easy to do because the inverse of $\boldsymbol{L}$ and $\boldsymbol{U}$ are simple. Thus the problem is reduced to solving one full matrix problem and then evaluating the solution for multiple right-hand sides. For implicit methods the same approach can be used, and the LU decomposition remains fixed until the time step is changed.

The *method of orthogonal collocation* uses a similar extension: the same polynomial of x is used but now the coefficients depend on time.

$$\left.\frac{\partial c}{\partial t}\right|_{x_j}=\frac{\mathrm{d}c\left(x_j,t\right)}{\mathrm{d}t}=\frac{\mathrm{d}c_j}{\mathrm{d}t}$$

Thus, for diffusion problems

$$\frac{\mathrm{d}c_j}{\mathrm{d}t}=\sum_{i=1}^{N+2}B_{ji}c_i,\ j=2,\ldots,N+1$$

This can be integrated by using the standard methods for ordinary differential equations as initial value problems. Stability limits for explicit methods are available [3, p. 204].

The method of orthogonal collocation on finite elements can also be used, and details are provided elsewhere [3, pp. 228 – 230].

The maximum eigenvalue for all the methods is given by

$$|\lambda|_{\max}=\frac{LB}{\Delta x^2} \tag{38}$$

where the values of LB are as follows:

Finite difference	4
Galerkin, linear elements, lumped	4
Galerkin, linear elements	12
Galerkin, quadratic elements	60
Orthogonal collocation on finite elements, cubic	36

Spectral methods employ the discrete Fourier transform (see 2 and Chebyshev polynomials on rectangular domains [116]).

In the Chebyshev collocation method, $N+1$ collocation points are used

$$x_j=\cos\frac{\pi j}{N},\ j=0,1,\ldots,N$$

As an example, consider the equation

$$\frac{\partial u}{\partial t}+f\left(u\right)\frac{\partial u}{\partial x}=0$$

An explicit method in time can be used

$$\frac{u^{n+1}-u^n}{\Delta t}+f\left(u^n\right)\left.\frac{\partial u}{\partial x}\right|^n=0$$

and evaluated at each collocation point

$$\frac{u_j^{n+1}-u_j^n}{\Delta t}+f\left(u_j^n\right)\left.\frac{\partial u}{\partial x}\right|_j^n=0$$

The trial function is taken as

$$u_j\left(t\right)=\sum_{p=0}^{N}a_p\left(t\right)\cos\frac{\pi pj}{N},\ u_j^n=u_j\left(t^n\right) \tag{39}$$

Assume that the values u_j^n exist at some time. Then invert Equation 39 using the fast Fourier transform to obtain $\{a_p\}$ for $p=0,1,\ldots,N$; then calculate S_p

$$S_p=S_{p+2}+\left(p+1\right)a_{p+1},\ 0\le p\le N-1$$

$$S_N=0,\ S_{N+1}=0$$

and finally

$$a_p^{(1)}=\frac{2S_p}{c_p}$$

Thus, the first derivative is given by

$$\left.\frac{\partial u}{\partial x}\right|_j=\sum_{p=0}^{N}a_p^{(1)}\left(t\right)\cos\frac{\pi pj}{N}$$

This is evaluated at the set of collocation points by using the fast Fourier transform again. Once the function and the derivative are known at each collocation point the solution can be advanced forward to the $n+1$-th time level.

The advantage of the spectral method is that it is very fast and can be adapted quite well to parallel computers. It is, however, restricted in the geometries that can be handled.

8.4. Elliptic Equations

Elliptic equations can be solved with both finite difference and finite element methods. One-dimensional elliptic problems are two-point boundary value problems and are covered in Chapter 7. Two-dimensional elliptic problems are often solved with direct methods, and iterative methods are usually used for three-dimensional problems. Thus, two aspects must be considered: how the equations are discretized to form sets of algebraic equations and how the algebraic equations are then solved.

The prototype elliptic problem is steady-state heat conduction or diffusion,

$$k\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}\right)=Q$$

possibly with a heat generation term per unit volume, Q. The boundary conditions can be

Dirichlet or 1st kind:	$T = T_1$ on boundary S_1
Neumann or 2nd kind:	$k\frac{\partial T}{\partial n}=q_2$ on boundary S_2
Robin, mixed, or 3rd kind:	$-k\frac{\partial T}{\partial n}=h\left(T-T_3\right)$ on boundary S_3

Illustrations are given for constant physical properties k, h, while T_1, q_2, T_3 are known functions on the boundary and Q is a known function of position. For clarity, only a two-dimensional problem is illustrated. The finite difference formulation is given by using the following nomenclature

$$T_{i,j}=T\left(i\Delta x,j\Delta y\right)$$

The finite difference formulation is then

$$\frac{T_{i+1,j}-2T_{i,j}+T_{i-1,j}}{\Delta x^2}+\frac{T_{i,j+1}-2T_{i,j}+T_{i,j-1}}{\Delta y^2}=Q_{i,j}/k \tag{40}$$

$$T_{i,j}=T_1 \text{ for } i,j \text{ on boundary } S_1$$

$$k\frac{\partial T}{\partial n}\Big|_{i,j}=q_2 \text{ for } i,j \text{ on boundary } S_2$$

$$-k\frac{\partial T}{\partial n}\Big|_{i,j}=h\left(T_{i,j}-T_3\right) \text{ for } i,j \text{ on boundary } S_3$$

If the boundary is parallel to a coordinate axis the boundary slope is evaluated as in Chapter 7, by using either a one-sided, centered difference or a false boundary. If the boundary is more irregular and not parallel to a coordinate line, more complicated expressions are needed and the finite element method may be the better method.

Equation 40 is rewritten in the form

$$2\left(1+\frac{\Delta x^2}{\Delta y^2}\right)T_{i,j}=T_{i+1,j}+T_{i-1,j}+\frac{\Delta x^2}{\Delta y^2}\left(T_{i,j+1}+T_{i,j-1}\right)-\Delta x^2\frac{Q_{i,j}}{k}$$

And this is converted to the Gauss–Seidel iterative method.

$$2\left(1+\frac{\Delta x^2}{\Delta y^2}\right)T_{i,j}^{s+1}=T_{i+1,j}^{s}+T_{i-1,j}^{s+1}+\frac{\Delta x^2}{\Delta y^2}\left(T_{i,j+1}^{s}+T_{i,j-1}^{s+1}\right)-\Delta x^2\frac{Q_{i,j}}{k}$$

Calculations proceed by setting a low i, computing from low to high j, then increasing i and repeating the procedure. The relaxation method uses

$$2\left(1+\frac{\Delta x^2}{\Delta y^2}\right)T_{i,j}^{*}=T_{i+1,j}^{s}+T_{i-1,j}^{s+1}+\frac{\Delta x^2}{\Delta y^2}\left(T_{i,j+1}^{s}-T_{i,j-1}^{s+1}\right)-\Delta x^2\frac{Q_{i,j}}{k}$$

$$T_{i,j}^{s+1}=T_{i,j}^{s}+\beta\left(T_{i,j}^{*}-T_{i,j}^{s}\right)$$

If $\beta = 1$, this is the Gauss – Seidel method. If $\beta > 1$, it is overrelaxation; if $\beta < 1$, it is underrelaxation. The value of β may be chosen empirically, $0 < \beta < 2$, but it can be selected theoretically for simple problems like this [117, p. 100], [3, p. 282]. In particular, the optimal value of the iteration parameter is given by

$$-\ln\left(\beta_{\text{opt}}-1\right)\approx R$$

and the error (in solving the algebraic equation) is decreased by the factor $(1 - R)^N$ for every N iterations. For the heat conduction problem and Dirichlet boundary conditions,

$$R=\frac{\pi^2}{2n^2}$$

(when there are n points in both x and y directions). For Neumann boundary conditions, the value is

$$R=\frac{\pi^2}{2n^2}\frac{1}{1+\max\left[\Delta x^2/\Delta y^2,\Delta y^2/\Delta x^2\right]}$$

Iterative methods can also be based on lines (for 2D problems) or planes (for 3D problems).

Preconditioned conjugate gradient methods have been developed (see Chap. 1). In these methods a series of matrix multiplications are done iteration by iteration; and the steps lend

themselves to the efficiency available in parallel computers. In the multigrid method the problem is solved on several grids, each more refined than the previous one. In iterating between the solutions on different grids, one converges to the solution of the algebraic equations. A chemical engineering application is given in [118]. Software for a variety of these methods is available, as described below.

The Galerkin finite element method (FEM) is useful for solving elliptic problems and is particularly effective when the domain or geometry is irregular [119 – 125]. As an example, cover the domain with triangles and define a trial function on each triangle. The trial function takes the value 1.0 at one corner and 0.0 at the other corners, and is linear in between (see Fig. 31). These trial functions on each triangle are pieced together to give a trial function on the whole domain. For the heat conduction problem the method gives [3]

Figure 31. Finite elements trial function: linear polynomials on triangles

$$\sum_e \sum_J A^e_{IJ} T^e_J = \sum_e \sum_J F^e_I \tag{41}$$

where

$$A^e_{IJ} = -\int k \nabla N_I \cdot \nabla N_J \mathrm{d}A - \int_{C_3} h_3 N_I N_J \mathrm{d}C$$

$$F^e_I = \int N_I Q \mathrm{d}A + \int_{C_2} N_I q_2 \mathrm{d}C - \int_{C_3} N_I h_3 T_3 \mathrm{d}C$$

Also, a necessary condition is that

$$T_i = T_1 \text{ on } C_1$$

In these equations I and J refer to the nodes of the triangle forming element e and the summation is made over all elements. These equations represent a large set of linear equations, which are solved using matrix techniques (Chap. 1).

If the problem is nonlinear, e.g., with k or Q a function of temperature, the equations must be solved iteratively. The integrals are given for a triangle with nodes I, J, and K in counterclockwise order. Within an element,

$$T = N_I(x,y)\,T_I + N_J(x,y)\,T_J + N_K(x,y)\,T_K$$

$$N_I = \frac{a_I + b_I\,x + c_I\,y}{2\Delta}$$

$$a_I = x_J\,y_K - x_K\,y_J$$

$$b_I = y_I - y_K$$

$$c_I = x_K - x_J$$

plus permutation on I, K, J

$$2\Delta = \det \begin{bmatrix} 1 & x_I & y_I \\ 1 & x_J & y_J \\ 1 & x_K & y_K \end{bmatrix} = 2\,(\text{area of triangle})$$

$$a_I + a_J + a_K = 1$$

$$b_I + b_J + b_K = 0$$

$$c_I + c_J + c_K = 0$$

$$A^e_{IJ} = -\frac{k}{4\Delta}\,(b_I\,b_J + c_I\,c_J)$$

$$F^e_{IJ} = \frac{Q}{2}\,(a_I + b_I\,\overline{x} + c_I\,\overline{y}) = \frac{QD}{3}$$

$$\overline{x} = \frac{x_I + x_J + x_K}{3},\ \overline{y} = \frac{y_I + y_J + y_K}{3}$$

$$a_I + b_I\,\overline{x} + c_I\,\overline{y} = \frac{2}{3}\Delta$$

The trial functions in the finite element method are not limited to linear ones. Quadratic functions, and even higher order functions, are frequently used. The same considerations hold as for boundary value problems: the higher order trial functions converge faster but require more work. It is possible to refine both the mesh (h) and power of polynomial in the trial function (p) in an hp method. Some problems have constraints on some of the variables. If singularities exist in the solution, it is possible to include them in the basis functions and solve for the difference between the total solution and the singular function [126 – 129].

When applying the Galerkin finite element method, one must choose both the shape of the element and the basis functions. In two dimensions, triangular elements are usually used because it is easy to cover complicated geometries and refine parts of the mesh. However, rectangular elements sometimes have advantages, par-

ticularly when some parts of the solution do not change very much and the elements can be long. In three dimensions the same considerations apply: tetrahedral elements are frequently used, but brick elements are also possible. While linear elements (in both two and three dimensions) are usually used, higher accuracy can be obtained by using quadratic or cubic basis functions within the element. The reason is that all methods converge according to the mesh size to some power, and the power is larger when higher order elements are used. If the solution is discontinuous, or has discontinuous first derivatives, then the lowest order basis functions are used because the convergence is limited by the properties of the solution, not the finite element approximation.

One nice feature of the finite element method is the use of natural boundary conditions. In this problem the natural boundary conditions are the Neumann or Robin conditions. When using Equation 41, the problem can be solved on a domain that is shorter than needed to reach some limiting condition (such as at an outflow boundary). The externally applied flux is still applied at the shorter domain, and the solution inside the truncated domain is still valid. Examples are given in [107] and [131]. The effect of this is to allow solutions in domains that are smaller, thus saving computation time and permitting the solution in semi-infinite domains.

8.5. Parabolic Equations in Two or Three Dimensions

Computations become much more lengthy with two or more spatial dimensions, for example, the unsteady heat conduction equation

$$\varrho C_p \frac{\partial T}{\partial t} = k\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}\right)-Q$$

or the unsteady diffusion equation

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 c}{\partial y^2}\right)-R(c)$$

In the finite difference method an explicit technique would evaluate the right-hand side at the n-th time level:

$$\rho C_p \frac{T_{i,j}^{n+1}-T_{i,j}^{n}}{\Delta t}$$
$$= \frac{k}{\Delta x^2}\left(T_{i+1,j}^{n}-2T_{i-1,j}^{n}+T_{i-1,j}^{n}\right)$$
$$+\frac{k}{\Delta y^2}\left(T_{i,j+1}^{n}-2T_{i,j}^{n}+T_{i,j-1}^{n}\right)-Q$$

When $Q = 0$ and $\Delta x = \Delta y$, the time step is limited by

$$\Delta t \leq \frac{\Delta x^2 \varrho C_p}{4k} \text{ or } \frac{\Delta x^2}{4D}$$

These time steps are smaller than for one-dimensional problems. For three dimensions, the limit is

$$\Delta t \leq \frac{\Delta x^2}{6D}$$

To avoid such small time steps, which must be smaller when Δx decreases, an implicit method could be used. This leads to large sparse matrices, rather than convenient tridiagonal matrices.

8.6. Special Methods for Fluid Mechanics

The method of operator splitting is also useful when different terms in the equation are best evaluated by using different methods or as a technique for reducing a larger problem to a series of smaller problems. Here the method is illustrated by using the Navier – Stokes equations. In vector notation the equations are

$$\varrho\frac{\partial \boldsymbol{u}}{\partial t}+\varrho\boldsymbol{u}\cdot\boldsymbol{\nabla}\boldsymbol{u} = \varrho\boldsymbol{f}-\boldsymbol{\nabla}p+\mu\nabla^2\boldsymbol{u}$$

The equation is solved in the following steps

$$\varrho\frac{\boldsymbol{u}^*-\boldsymbol{u}^n}{\Delta t} = -\varrho\boldsymbol{u}^n\cdot\boldsymbol{\nabla}\boldsymbol{u}^n+\varrho\boldsymbol{f}+\mu\nabla^2\boldsymbol{u}^n$$

$$\nabla^2 p^{n+1} = \frac{1}{\Delta t}\boldsymbol{\nabla}\cdot\boldsymbol{u}^*$$

$$\varrho\frac{\boldsymbol{u}^{n+1}-\boldsymbol{u}^*}{\Delta t} = -\boldsymbol{\nabla}p$$

This can be done by using the finite difference [132, p. 162] or the finite element method [133 – 135].

In fluid flow problems solved with the finite element method, the basis functions for pressure and velocity are often different. This is required by the LBB condition (named after Ladyshenskaya, Brezzi, and Babuska) [134, 135]. Sometimes a discontinuous basis function is used for pressure to meet this condition. Other times a

penalty term is added, or the quadrature is done using a small number of quadrature points. Thus, one has to be careful how to apply the finite element method to the Navier – Stokes equations. Fortunately, software exists that has taken this into account.

Level Set Methods. Multiphase problems are complicated because the terms in the equations depend on which phase exists at a particular point, and the phase boundary may move or be unknown. It is desirable to compute on a fixed grid, and the level set formulation allows this. Consider a curved line in a two-dimensional problem or a curved surface in a three-dimensional problem. One defines a level set function ϕ, which is the signed distance function giving the distance from some point to the closest point on the line or surface. It defined to be negative on one side of the interface and positive on the other. Then the curve

$$\phi(x,y,z) = 0$$

represents the location of the interface. For example, in flow problems the level set function is defined as the solution to

$$\frac{\partial \phi}{\partial t} + \boldsymbol{u} \cdot \boldsymbol{\nabla} \phi = 0$$

The physics governing the velocity of the interface must be defined, and this equation is solved along with the other equations representing the problem [130 – 137].

Lattice Boltzmann Methods. Another way to solve fluid flow problems is based on a molecular viewpoint and is called the Lattice Boltzmann method [138 – 141]. The treatment here follows [142]. A lattice is defined, and one solves the following equation for $f_i\,(x,t)$, the probability of finding a molecule at the point x with speed c_i.

$$\frac{\partial f_i}{\partial t} + c_i \cdot \boldsymbol{\nabla} f_i = -\frac{f_i - f_i^{\mathrm{eq}}}{\tau}$$

The right-hand side represents a single time relaxation for molecular collisions, and τ is related to the kinematic viscosity. By means of a simple stepping algorithm, the computational algorithm is

$$f_i(\mathbf{x} + \mathbf{c}_i \Delta t, t + \Delta t) = f_i(\mathbf{x}, t) - \frac{\Delta t}{\tau}(f_i - f_i^{\mathrm{eq}})$$

Consider the lattice shown in Figure 32. The various velocities are

$$c_1 = (1,0), c_3 = (0,1), c_5 = (-1,0), c_7 = (0,-1)$$

$$c_2 = (1,1), c_4 = (-1,1), c_6 = (-1,-1), c_8 = (1,-1)$$

$$c_0 = (0,0)$$

The density, velocity, and shear stress (for some k) are given by

$$\rho = \sum\nolimits_i f_i(\boldsymbol{x},t), \rho \mathbf{u} = \sum\nolimits_i \boldsymbol{c}_i f_i(\boldsymbol{x},t),$$

$$\tau = k \sum\nolimits_i \boldsymbol{c}_i \boldsymbol{c}_i \left[f_i(\boldsymbol{x},t) - f_i^{\mathrm{eq}}(\boldsymbol{x},t) \right]$$

For this formulation, the kinematic viscosity and speed of sound are given by

$$\nu = \frac{1}{3}(\tau - \frac{1}{2}), c_s = \frac{1}{3}$$

The equilibrium distribution is

$$f_i^{\mathrm{eq}} = \rho w_i \left[1 + \frac{\boldsymbol{c}_i \cdot \mathbf{u}}{c_s^2} + \frac{(\boldsymbol{c}_i \cdot \mathbf{u})^2}{2c_s^4} - \frac{\mathbf{u} \cdot \mathbf{u}}{2c_s^2} \right]$$

where the weighting functions are

$$w_0 = \frac{4}{9}, w_1 = w_3 = w_5 = w_7 = \frac{1}{9},$$
$$w_2 = w_4 = w_6 = w_8 = \frac{1}{36}$$

With these conditions, the solution for velocity is a solution of the Navier—Stokes equation. These equations lead to a large computational problem, but it can be solved by parallel processing on multiple computers.

Figure 32.

8.7. Computer Software

A variety of general-purpose computer programs are available commercially. Mathematica (http://www.wolfram.com/), Maple (http://www.maplesoft.com/) and Mathcad (http://www.mathcad.com/) all have the capability of doing symbolic manipulation so that algebraic solutions can be obtained. For example, Mathematica can solve some ordinary and partial differential equations analytically; Maple can make simple graphs and do linear algebra and simple computations, and Mathcad can do simple calculations. In this section, examples are given for the use of Matlab (http://www.mathworks.com/), which is a package of numerical analysis tools, some of which are accessed by simple commands, and some of which are accessed by writing programs in C. Spreadsheets can also be used to solve simple problems. A popular program used in chemical engineering education is Polymath (http://www.polymath-software.com/), which can numerically solve sets of linear or nonlinear equations, ordinary differential equations as initial value problems, and perform data analysis and regression.

The mathematical methods used to solve partial differential equations are described in more detail in [143 – 148]. Since many computer programs are available without cost, consider the following decision points. The first decision is whether to use an approximate, engineering flow model, developed from correlations, or to solve the partial differential equations that govern the problem. Correlations are quick and easy to apply, but they may not be appropriate to your problem, or give the needed detail. When using a computer package to solve partial differential equations, the first task is always to generate a mesh covering the problem domain. This is not a trivial task, and special methods have been developed to permit importation of a geometry from a computer-aided design program. Then, the mesh must be created automatically. If the boundary is irregular, the finite element method is especially well-suited, although special embedding techniques can be used in finite difference methods (which are designed to be solved on rectangular meshes). Another capability to consider is the ability to track free surfaces that move during the computation. This phenomenon introduces the same complexity that occurs in problems with a large Peclet number, with the added difficulty that the free surface moves between mesh points, and improper representation can lead to unphysical oscillations. The method used to solve the equations is important, and both explicit and implicit methods (as described above) can be used. Implicit methods may introduce unacceptable extra diffusion, so the engineer needs to examine the solution carefully. The methods used to smooth unphysical oscillations from node to node are also important, and the engineer needs to verify that the added diffusion or smoothing does not give inaccurate solutions. Since current-day problems are mostly nonlinear, convergence is always an issue since the problems are solved iteratively. Robust programs provide several methods for convergence, each of which is best in some circumstance or other. It is wise to have a program that includes many iterative methods. If the iterative solver is not very robust, the only recourse to solving a steady-state problem may be to integrate the time-dependent problem to steady state. The solution time may be long, and the final result may be further from convergence than would be the case if a robust iterative solver were used.

A variety of computer programs is available on the internet, some of them free. First consider general-purpose programs. On the NIST web page, http://gams.nist.gov/ choose "problem decision tree", and then "differential and integral equations", then "partial differential equations". The programs are organized by type of problem (elliptic, parabolic, and hyperbolic) and by the number of spatial dimensions (one or more than one). On the Netlib web site, http://www.netlib.org/, search on "partial differential equation". The website: http://software.sandia.gov has a variety of programs available. Lau [141, 145] provides many programs in C++ (also see http://www.nr.com/). The multiphysics program Comsol Multiphysics (formerly FEMLAB) also solves many standard equations arising in Mathematical Physics.

Computational fluid dynamics (CFD) programs are more specialized, and most of them have been designed to solve sets of equations that are appropriate to specific industries. They can then include approximations and correlations for some features that would be difficult to solve for directly. Four widely used major packages are

Fluent (http://www.fluent.com/), CFX (now part of ANSYS), Comsol Multiphysics (formerly FEMLAB) (http://www.comsol.com/), and ANSYS (http://www.ansys.com/). Of these, Comsol Multiphysics is particularly useful because it has a convenient graphical user interface, permits easy mesh generation and refinement (including adaptive mesh refinement), allows the user to add in phenomena and additional equations easily, permits solution by continuation methods (thus enhancing convergence), and has extensive graphical output capabilities. Other packages are also available (see http://cfd-online.com/), and these may contain features and correlations specific to the engineer's industry. One important point to note is that for turbulent flow, all the programs contain approximations, using the k-epsilon models of turbulence, or large eddy simulations; the direct numerical simulation of turbulence is too slow to apply it to very big problems, although it does give insight (independent of any approximations) that is useful for interpreting turbulent phenomena. Thus, the method used to include those turbulent correlations is important, and the method also may affect convergence or accuracy.

9. Integral Equations [149 – 155]

If the dependent variable appears under an integral sign an equation is called an integral equation; if derivatives of the dependent variable appear elsewhere in the equation it is called an integrodifferential equation. This chapter describes the various classes of equations, gives information concerning Green's functions, and presents numerical methods for solving integral equations.

9.1. Classification

Volterra integral equations have an integral with a variable limit, whereas Fredholm integral equations have a fixed limit. Volterra equations are usually associated with initial value or evolutionary problems, whereas Fredholm equations are analogous to boundary value problems. The terms in the integral can be unbounded, but still yield bounded integrals, and these equations are said to be weakly singular. A *Volterra equation of the second kind* is

$$y(t) = g(t) + \lambda \int_a^t K(t,s) y(s)\,\mathrm{d}s \tag{42}$$

whereas a *Volterra equation of the first kind* is

$$y(t) = \lambda \int_a^t K(t,s)\, y(s)\,\mathrm{d}s$$

Equations of the first kind are very sensitive to solution errors so that they present severe numerical problems.

An example of a problem giving rise to a Volterra equation of the second kind is the following heat conduction problem:

$$\varrho C_p \frac{\partial T}{\partial t} = k \frac{\partial^2 T}{\partial x^2},\ 0 \le x < \infty,\ t > 0$$

$$T(x,0) = 0,\ \frac{\partial T}{\partial x}(0,t) = -g(t),$$

$$\lim_{x\to\infty} T(x,t) = 0,\ \lim_{x\to\infty} \frac{\partial T}{\partial x} = 0$$

If this is solved by using Fourier transforms the solution is

$$T(x,t) = \frac{1}{\sqrt{\pi}} \int_0^t g(s) \frac{1}{\sqrt{t-s}} \mathrm{e}^{-x^2/4(t-s)}\mathrm{d}s$$

Suppose the problem is generalized so that the boundary condition is one involving the solution T, which might occur with a radiation boundary condition or heat-transfer coefficient. Then the boundary condition is written as

$$\frac{\partial T}{\partial x} = -G(T,t),\ x = 0,\ t > 0$$

The solution to this problem is

$$T(x,t) = \frac{1}{\sqrt{\pi}} \int_0^t G(T(0,s),s) \frac{1}{\sqrt{t-s}}\, \mathrm{e}^{-x^2/4(t-s)}\mathrm{d}s$$

If $T^*(t)$ is used to represent $T(0, t)$, then

$$T^*(t) = \frac{1}{\sqrt{\pi}} \int_0^t G(\boldsymbol{T}(s),s) \frac{1}{\sqrt{t-s}}\mathrm{d}s$$

Thus the behavior of the solution at the boundary is governed by an integral equation. Nagel and Kluge [156] use a similar approach to solve for adsorption in a porous catalyst.

The existence and uniqueness of the solution can be proved [151, p. 30, 32].

Sometimes the kernel is of the form

$$K(t,s) = K(t-s)$$

Equations of this form are called convolution equations and can be solved by taking the Laplace transform. For the integral equation

$$Y(t) = G(t) + \lambda \int_0^t K(t-\tau)\, Y(\tau)\, \mathrm{d}\tau$$

$$K(t) * Y(t) \equiv \int_0^t K(t-\tau)\, Y(\tau)\, \mathrm{d}\tau$$

the Laplace transform is

$$y(s) = g(s) + k(s)\, y(s)$$

$$k(s)\, y(s) = \boldsymbol{L}[K(t) * Y(t)]$$

Solving this for $y(s)$ gives

$$y(s) = \frac{g(s)}{1-k(s)}$$

If the inverse transform can be found, the integral equation is solved.

A *Fredholm equation of the second kind* is

$$y(x) = g(x) + \lambda \int_a^b K(x,s)\, y(s)\, \mathrm{d}s \tag{43}$$

whereas a *Fredholm equation of the first kind* is

$$\int_a^b K(x,s)\, y(s)\, \mathrm{d}s = g(x)$$

The limits of integration are fixed, and these problems are analogous to boundary value problems. An eigenvalue problem is a homogeneous equation of the second kind.

$$y(x) = \lambda \int_a^b K(x,s)\, y(s)\, \mathrm{d}s \tag{44}$$

Solutions to this problem occur only for specific values of λ, the eigenvalues. Usually the Fredholm equation of the second or first kind is solved for values of λ different from these, which are called regular values.

Nonlinear Volterra equations arise naturally from initial value problems. For the initial value problem

$$\frac{\mathrm{d}y}{\mathrm{d}t} = F(t, y(t))$$

both sides can be integrated from 0 to t to obtain

$$y(t) = y(0) + \int_0^t F(s, y(s))\, \mathrm{d}s$$

which is a nonlinear Volterra equation. The general nonlinear Volterra equation is

$$y(t) = g(t) + \int_0^t K(t,s,y(s))\, \mathrm{d}s \tag{45}$$

Theorem [151, *p. 55].* If $g(t)$ is continuous, the kernel $K(t, s, y)$ is continuous in all variables and satisfies a Lipschitz condition

$$|K(t,s,y) - K(t,s,z)| \le L\, |y-z|$$

then the nonlinear Volterra equation has a unique continuous solution.

A successive substitution method for its solution is

$$y_{n+1}(t) = g(t) + \int_0^t K[t,s,y_n(s)]\, \mathrm{d}s$$

Nonlinear Fredholm equations have special names. The equation

$$f(x) = \int_0^1 K[x,y,f(y)]\, \mathrm{d}y$$

is called the Urysohn equation [150 p. 208]. The special equation

$$f(x) = \int_0^1 K[x,y]\, F[y,f(y)]\, \mathrm{d}y$$

is called the Hammerstein equation [150, p. 209]. Iterative methods can be used to solve these equations, and these methods are closely tied to fixed point problems. A fixed point problem is

$$x = F(x)$$

and a successive substitution method is

$$x_{n+1} = F(x_n)$$

Local convergence theorems prove the process convergent if the solution is close enough to the answer, whereas global convergence theorems are valid for any initial guess [150, p. 229 – 231]. The successive substitution method for nonlinear Fredholm equations is

$$y_{n+1}(x) = \int_0^1 K[x,s,y_n(s)]\, \mathrm{d}s$$

Typical conditions for convergence include that the function satisfies a Lipschitz condition.

9.2. Numerical Methods for Volterra Equations of the Second Kind

Volterra equations of the second kind are analogous to initial value problems. An initial value problem can be written as a Volterra equation of the second kind, although not all Volterra equations can be written as initial value problems [151, p. 7]. Here the general nonlinear Volterra equation of the second kind is treated (Eq. 45). The simplest numerical method involves replacing the integral by a quadrature using the trapezoid rule.

$$y_n \equiv y(t_n) = g(t_n) + \Delta t \left\{ \frac{1}{2} K(t_n, t_0, y_0) + \sum_{i=1}^{n-1} K(t_n, t_i, y_i) + \frac{1}{2} K(t_n, t_n, y_n) \right\}$$

This equation is a nonlinear algebraic equation for y_n. Since y_0 is known it can be applied to solve for y_1, y_2, ... in succession. For a single integral equation, at each step one must solve a single nonlinear algebraic equation for y_n. Typically, the error in the solution to the integral equation is proportional to Δt^{μ}, and the power μ is the same as the power in the quadrature error [151, p. 97].

The stability of the method [151, p. 111] can be examined by considering the equation

$$y(t) = 1 - \lambda \int_0^t y(s)\,\mathrm{d}s$$

whose solution is

$$y(t) = \mathrm{e}^{-\lambda t}$$

Since the integral equation can be differentiated to obtain the initial value problem

$$\frac{\mathrm{d}y}{\mathrm{d}t} = -\lambda y,\ y(0) = 1$$

the stability results are identical to those for initial value methods. In particular, using the trapezoid rule for integral equations is identical to using this rule for initial value problems. The method is A-stable.

Higher order integration methods can also be used [151, p. 114, 124]. When the kernel is infinite at certain points, i.e., when the problem has a weak singularity, see [151, p. 71, 151].

9.3. Numerical Methods for Fredholm, Urysohn, and Hammerstein Equations of the Second Kind

Whereas Volterra equations could be solved from one position to the next, like initial value differential equations, Fredholm equations must be solved over the entire domain, like boundary value differential equations. Thus, large sets of equations will be solved and the notation is designed to emphasize that.

The methods are also based on quadrature formulas. For the integral

$$I(\varphi) = \int_a^b \varphi(y)\,\mathrm{d}y$$

a quadrature formula is written:

$$I(\varphi) = \sum_{i=0}^{n} w_i \varphi(y_i)$$

Then the integral Fredholm equation can be rewritten as

$$f(x) - \lambda \sum_{i=0}^{n} w_i K(x, y_i) f(y_i) = g(x), \quad a \le x \le b \tag{46}$$

If this equation is evaluated at the points $x = y_j$,

$$f(y_j) - \lambda \sum_{i=0}^{n} w_i K(y_j, y_i) f(y_i) = g(y_i)$$

is obtained, which is a set of linear equations to be solved for $\{f(y_j)\}$. The solution at any point is then given by Equation 46.

A common type of integral equation has a singular kernel along $x = y$. This can be transformed to a less severe singularity by writing

$$\int_a^b K(x,y) f(y)\,\mathrm{d}y = \int_a^b K(x,y)\,[f(y) - f(x)]\,\mathrm{d}y + \int_a^b K(x,y) f(x)\,\mathrm{d}y = \int_a^b K(x,y)\,[f(y) - f(x)]\,\mathrm{d}y + f(x) H(x)$$

where

$$H(x) = \int_a^b K(x,y) f(x)\,\mathrm{d}y$$

is a known function. The integral equation is then replaced by

$$f(x) = g(x) + \sum_{i=0}^{n} w_i K(x,y_i)\,[f(y_i) - f(x)] + f(x)\,H(x)$$

Collocation methods can be applied as well [149, p. 396]. To solve integral Equation 43 expand f in the function

$$f = \sum_{i=0}^{n} a_i \varphi_i(x)$$

Substitute f into the equation to form the residual

$$\sum_{i=0}^{n} a_i \varphi_i(x) - \lambda \sum_{i=0}^{n} a_i \int_a^b K(x,y)\,\varphi_i(y)\,\mathrm{d}y = g(x)$$

Evaluate the residual at the collocation points

$$\sum_{i=0}^{n} a_i \varphi_i(x_j) - \lambda \sum_{i=0}^{n} a_i \int_a^b K(x_j,y)\,\varphi_i(y)\,\mathrm{d}y = g(x_j)$$

The expansion can be in piecewise polynomials, leading to a collocation finite element method, or global polynomials, leading to a global approximation. If orthogonal polynomials are used then the quadratures can make use of the accurate Gaussian quadrature points to calculate the integrals. Galerkin methods are also possible [149, p. 406]. MILLS et al. [157] consider reaction – diffusion problems and say the choice of technique cannot be made in general because it is highly dependent on the kernel.

When the integral equation is nonlinear, iterative methods must be used to solve it. Convergence proofs are available, based on Banach's contractive mapping principle. Consider the Urysohn equation, with $g(x) = 0$ without loss of generality:

$$f(x) = \int_a^b F[x,y,f(y)]\,\mathrm{d}y$$

The kernel satisfies the Lipschitz condition

$$\max_{a \le x, y \le b} |F[x,y,f(y)] - F[x,z,f(z)]| \le K\,|y-z|$$

Theorem [150, p. 214]. If the constant K is $<$ 1 and certain other conditions hold, the successive substitution method

$$f_{n+1}(x) = \int_a^b F[x,y,f_n(y)]\,\mathrm{d}y, n = 0,1\ldots$$

converges to the solution of the integral equations.

9.4. Numerical Methods for Eigenvalue Problems

Eigenvalue problems are treated similarly to Fredholm equations, except that the final equation is a matrix eigenvalue problem instead of a set of simultaneous equations. For example,

$$\sum_{i=1}^{n} w_i K(y_i,y_i)\,f(y_i) = \lambda f(y_j),$$
$$i = 0,1,\ldots,n$$

leads to the matrix eigenvalue problem

$$\boldsymbol{K}\,\boldsymbol{D}\,\boldsymbol{f} = \lambda \boldsymbol{f}$$

Where $\boldsymbol{D}$ is a diagonal matrix with $D_{ii} = w_i$.

9.5. Green's Functions [158 – 160]

Integral equations can arise from the formulation of a problem by using Green's function. For example, the equation governing heat conduction with a variable heat generation rate is represented in differential forms as

$$\frac{\mathrm{d}^2 T}{\mathrm{d}x^2} = \frac{Q(x)}{k},\ T(0) = T(1) = 0$$

In integral form the same problem is [149, pp. 57 – 60]

$$T(x) = \frac{1}{k}\int_0^1 G(x,y)\,Q(y)\,\mathrm{d}y$$

$$G(x,y) = \begin{cases} -x(1-y) & x \le y \\ -y(1-x) & y \le x \end{cases}$$

Green's functions for typical operators are given below.

For the Poisson equation with solution decaying to zero at infinity

$$\nabla^2 \psi = -4\pi\varrho$$

the formulation as an integral equation is

$$\psi(\boldsymbol{r}) = \int_V \rho(\boldsymbol{r}_0)\,G(\boldsymbol{r},\boldsymbol{r}_0)\,\mathrm{d}V_0$$

where Green's function is [50, p. 891]

$G(\boldsymbol{r},\boldsymbol{r}_0) = \frac{1}{r}$ in three dimensions

$= -2\ln r$ in two dimensions

where $r = \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2}$ in three dimensions

and $r = \sqrt{(x-x_0)^2 + (y-x_0)^2}$ in two dimensions

For the problem

$$\frac{\partial u}{\partial t} = D\nabla^2 u,\ u = 0 \text{ on } S,$$

with a point source at x_0, y_0, z_0

Green's function is [44, p. 355]

$$u = \frac{1}{8[\pi D(t-\tau)]^{3/2}}$$

$$\mathrm{e}^{-\left[(x-x_0)^2+(y-y_0)^2+(z-z_0)^2\right]/4\,D(t-\tau)}$$

When the problem is

$$\frac{\partial c}{\partial t} = D\nabla^2 c$$

$$c = f\,(x,y,z) \text{ in } S \text{ at } t = 0$$

$$c = \varphi\,(x,y,z) \text{ on } S, t>0$$

the solution can be represented as [44, p. 353]

$$c = \int\int\int (u)_{\tau=0} f\,(x,y,z)\,\mathrm{d}x\mathrm{d}y\mathrm{d}z$$

$$+D\int_0^t\int\int\int \varphi\,(x,y,z,\tau)\,\frac{\partial u}{\partial n}\mathrm{d}S\mathrm{d}t$$

When the problem is two dimensional,

$$u = \frac{1}{\sqrt{4\pi D(t-\tau)}}\mathrm{e}^{-\left[(x-x_0)^2+(y-y_0)^2\right]/4D(t-\tau)}$$

$$c = \int\int (u)_{\tau=0} f\,(x,y)\,\mathrm{d}x\mathrm{d}y$$

$$+D\int_0^t\int \varphi\,(x,y,\tau)\,\frac{\partial u}{\partial n}\mathrm{d}C\mathrm{d}t$$

For the following differential equation and boundary conditions

$$\frac{1}{x^{a-1}}\frac{\mathrm{d}}{\mathrm{d}x}\left(x^{\mathrm{a}-1}\frac{\mathrm{d}c}{\mathrm{d}x}\right) = f\,[x,c\,(x)]\,,$$

$$\frac{\mathrm{d}c}{\mathrm{d}x}\,(0) = 0,\ \frac{2}{Sh}\frac{\mathrm{d}c}{\mathrm{d}x}\,(1) + c\,(1) = g$$

where *Sh* is the Sherwood number, the problem can be written as a Hammerstein integral equation:

$$c\,(x) = g - \int_0^1 G\,(x,y,Sh)\,f\,[y,c\,(y)]\,y^{a-1}\mathrm{d}y$$

Green's function for the differential operators are [163]

$a = 1$

$$G\,(x,y,Sh) = \begin{cases} 1+\frac{2}{Sh}-x, & y\le x \\ 1+\frac{2}{Sh}-y, & x<y \end{cases}$$

$a = 2$

$$G\,(x,y,Sh) = \begin{cases} \frac{2}{Sh}-\ln x, & y\le x \\ \frac{2}{Sh}-\ln y, & x<y \end{cases}$$

$a = 3$

$$G\,(x,y,Sh) = \begin{cases} \frac{2}{Sh}+\frac{1}{x}-1, & y\le x \\ \frac{2}{Sh}+\frac{1}{y}-1, & x<y \end{cases}$$

Green's functions for the reaction diffusion problem were used to provide computable error bounds by Ferguson and Finlayson [163].

If Green's function has the form

$$K\,(x,y) = \begin{cases} u\,(x)\,v\,(y) & 0\le y\le x \\ u\,(y)\,v\,(x) & x\le y\le 1 \end{cases}$$

the problem

$$f\,(x) = \int_0^1 K\,(x,y)\,F\,[y,f\,(y)]\,\mathrm{d}y$$

may be written as

$$f\,(x) - \int_0^x [u\,(x)\,v\,(y) - u\,(y)\,v\,(x)]\cdot$$

$$f\,[y,f\,(y)]\,\mathrm{d}y = \alpha v\,(x)$$

where

$$\alpha = \int_0^1 u\,(y)\,F\,[y,f\,(y)]\,\mathrm{d}y$$

Thus, the problem ends up as one directly formulated as a fixed point problem:

$$f = \Phi\,(f)$$

When the problem is the diffusion – reaction one, the form is

$$c\,(x) = g - \int_0^x [u\,(x)\,v\,(y) - u\,(y)\,v\,(x)]$$

$$f\,[y,c\,(y)]\,y^{a-1}\mathrm{d}y - \alpha v\,(x)$$

$$\alpha = \int_0^1 u\,(y)\,f\,[y,c\,(y)]\,y^{a-1}\mathrm{d}y$$

Dixit and Taularidis [164] solved problems involving Fischer – Tropsch synthesis reactions in a catalyst pellet using a similar method.

9.6. Boundary Integral Equations and Boundary Element Method

The boundary element method utilizes Green's theorem and integral equations. Here, the method is described briefly for the following boundary value problem in two or three dimensions

$$\nabla^2\varphi = 0,\ \varphi = f_1 \text{ on } S_1,\ \frac{\partial\varphi}{\partial n} = f_2 \text{ on } S_2$$

Green's theorem (see page 44) says that for any functions sufficiently smooth

$$\int_V \left(\varphi\nabla^2\psi - \psi\nabla^2\varphi\right) \mathrm{d}V = \int_S \left(\varphi\frac{\partial\psi}{\partial n} - \psi\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S$$

Suppose the function ψ satisfies the equation

$$\nabla^2\psi = 0$$

In two and three dimensions, such a function is

$$\psi = \ln r,\ r = \sqrt{(x-x_0)^2 + (y-y_0)^2}$$

in two dimensions

$$\psi = \tfrac{1}{r},\ r = \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2}$$

in three dimensions

where $\{x_0, y_0\}$ or $\{x_0, y_0, z_0\}$ is a point in the domain. The solution φ also satisfies

$$\nabla^2\varphi = 0$$

so that

$$\int_S \left(\varphi\frac{\partial\psi}{\partial n} - \psi\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S = 0$$

Consider the two-dimensional case. Since the function ψ is singular at a point, the integrals must be carefully evaluated. For the region shown in Figure 33, the domain is $S = S_1 + S_2$; a small circle of radius r_0 is placed around the point P at x_0, y_0. Then the full integral is

$$\int_S \left(\varphi\frac{\partial \ln r}{\partial n} - \ln r\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S + \int_{\theta=0}^{\theta=2\pi} \left(\varphi\frac{\partial \ln r_0}{\partial n} - \ln r_0\frac{\partial\varphi}{\partial n}\right) r_0 \mathrm{d}\theta = 0$$

As r_0 approaches 0,

$$\lim_{r_0\to 0} r_0 \ln r_0 = 0$$

and

$$\lim_{r_0\to 0} \int_{\theta=0}^{\theta=2\pi} \varphi\frac{\partial \ln r_0}{\partial n} r_0 \mathrm{d}\theta = -\varphi(P)\, 2\pi$$

Thus for an internal point,

$$\varphi(P) = \frac{1}{2\pi}\int_S \left(\varphi\frac{\partial \ln r}{\partial n} - \ln r\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S \tag{47}$$

If P is on the boundary, the result is [165, p. 464]

$$\varphi(P) = \frac{1}{\pi}\int_S \left(\varphi\frac{\partial \ln r}{\partial n} - \ln r\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S$$

Putting in the boundary conditions gives

$$\pi\varphi(P) = \int_{S_1} \left(f_1\frac{\partial \ln r}{\partial n} - \ln r\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S + \int_{S_2} \left(\varphi\frac{\partial \ln r}{\partial n} - f_2 \ln r\right) \mathrm{d}S \tag{48}$$

This is an integral equation for φ on the boundary. Note that the order is one less than the original differential equation. However, the integral equation leads to matrices that are dense rather than banded or sparse, so some of the advantage of lower dimension is lost. Once this integral equation (Eq. 48) is solved to find φ on the boundary, it can be substituted in Equation 47 to find φ anywhere in the domain.

Figure 33. Domain with singularity at P

In the boundary finite element method, both the function and its normal derivative along the boundary are approximated.

$$\varphi = \sum_{j=1}^{N} \varphi_j N_j(\xi),\ \frac{\partial\varphi}{\partial n} = \sum_{j=1}^{N} \left(\frac{\partial\varphi}{\partial n}\right)_j N_j(\xi)$$

One choice of trial functions can be the piecewise constant functions shown in Figure 34. The integral equation then becomes

Figure 34. Trial function on boundary for boundary finite element method

$$\pi\varphi_i \sum_{j=1}^{N} \left[\varphi_j \int_{s_j} \frac{\partial \ln r_i}{\partial n} \mathrm{d}S - \left(\frac{\partial \varphi_j}{\partial n} \right) \int_{s_j} \ln r_i \right] \mathrm{d}s$$

The function φ_j is of course known along s_1, whereas the derivative $\partial\varphi_j/\partial n$ is known along s_2. This set of equations is then solved for φ_i and $\partial\varphi_i/\partial n$ along the boundary. This constitutes the boundary integral method applied to the Laplace equation.

If the problem is Poisson's equation

$$\nabla^2\varphi = g\,(x,y)$$

Green's theorem gives

$$\int_S \left(\varphi \frac{\partial \ln r}{\partial n} - \ln r \frac{\partial \varphi}{\partial n} \right) \mathrm{d}S + \int_A g \ln r \,\mathrm{d}A = 0$$

Thus, for an internal point,

$$2\pi\varphi\,(P) = \int_S \left(\varphi \frac{\partial \ln r}{\partial r} - \ln r \frac{\partial \varphi}{\partial n} \right) \mathrm{d}S + \int_A g \ln r \mathrm{d}A \tag{49}$$

and for a boundary point,

$$\pi\varphi\,(P) = \int_S \left(\varphi \frac{\partial \ln r}{\partial n} - \ln r \frac{\partial \varphi}{\partial n} \right) \mathrm{d}S + \int_A g \ln r \mathrm{d}A \tag{50}$$

If the region is nonhomogeneous this method can be used [165, p. 475], and it has been applied to heat conduction by Hsieh and Shang [166]. The finite element method can be applied in one region and the boundary finite element method in another region, with appropriate matching conditions [165, p. 478]. If the problem is nonlinear, then it is more difficult. For example, consider an equation such as Poisson's in which the function depends on the solution as well

$$\nabla^2\varphi = g\,(x,y,\varphi)$$

Then the integral appearing in Equation 50 must be evaluated over the entire domain, and the solution in the interior is given by Equation 49. For further applications, see [167] and [168].

10. Optimization

We provide a survey of systematic methods for a broad variety of optimization problems. The survey begins with a general classification of mathematical optimization problems involving continuous and discrete (or integer) variables. This is followed by a review of solution methods of the major types of optimization problems for continuous and discrete variable optimization, particularly nonlinear and mixed-integer nonlinear programming. In addition, we discuss direct search methods that do not require derivative information as well as global optimization methods. We also review extensions of these methods for the optimization of systems described by differential and algebraic equations.

10.1. Introduction

Optimization is a key enabling tool for decision making in chemical engineering [306]. It has evolved from a methodology of academic interest into a technology that continues to make significant impact in engineering research and practice. Optimization algorithms form the core tools for a) experimental design, parameter estimation, model development, and statistical analysis; b) process synthesis analysis, design, and retrofit; c) model predictive control and real-time optimization; and d) planning, scheduling, and the integration of process operations into the supply chain [307, 308].

As shown in Figure 35, optimization problems that arise in chemical engineering can be classified in terms of continuous and discrete variables. For the former, nonlinear programming (NLP) problems form the most general case, and widely applied specializations include linear programming (LP) and quadratic programming (QP). An important distinction for NLP is whether the optimization problem is convex or nonconvex. The latter NLP problem may

have multiple local optima, and an important question is whether a global solution is required for the NLP. Another important distinction is whether the problem is assumed to be differentiable or not.

Mixed-integer problems also include discrete variables. These can be written as mixed-integer nonlinear programs (MINLP) or as mixed-integer linear programs (MILP) if all variables appear linearly in the constraint and objective functions. For the latter an important case occurs when all the variables are integer; this gives rise to an integer programming (IP) problem. IPs can be further classified into many special problems (e.g., assignment, traveling salesman, etc.), which are not shown in Figure 35. Similarly, the MINLP problem also gives rise to special problem classes, although here the main distinction is whether its relaxation is convex or nonconvex.

The ingredients of formulating optimization problems include a mathematical model of the system, an objective function that quantifies a criterion to be extremized, variables that can serve as decisions, and, optionally, inequality constraints on the system. When represented in algebraic form, the general formulation of discrete/continuous optimization problems can be written as the following mixed-integer optimization problem:

$$\begin{aligned} \text{Min} \quad & f(x,y) \\ \text{s.t.} \quad & h(x,y) = 0 \\ & g(x,y) \leq 0 \\ & x \in \Re^n, y \in \{0,1\}^t \end{aligned} \tag{51}$$

where $f(x, y)$ is the objective function (e.g., cost, energy consumption, etc.), $h(x, y) = 0$ are the equations that describe the performance of the system (e.g., material balances, production rates), the inequality constraints $g(x, y) \leq 0$ can define process specifications or constraints for feasible plans and schedules, and s.t. denotes subject to. Note that the operator Max $f(x)$ is equivalent to Min $-f(x)$. We define the real n-vector x to represent the continuous variables while the t-vector y represents the discrete variables, which, without loss of generality, are often restricted to take 0–1 values to define logical or discrete decisions, such as assignment of equipment and sequencing of tasks. (These variables can also be formulated to take on other integer values as well.) Problem 51 corresponds to a mixed-integer nonlinear program (MINLP) when any of the functions involved are nonlinear. If all functions are linear it corresponds to a mixed-integer linear program (MILP). If there are no 0–1 variables, then problem 51 reduces to a nonlinear program 52 or linear program 65 depending on whether or not the functions are linear.

Figure 35. Classes of optimization problems and algorithms

We first start with continuous variable optimization and consider in the next section the solution of NLPs with differentiable objective and constraint functions. If only local solutions are required for the NLP, then very efficient large-scale methods can be considered. This is followed by methods that are not based on local optimality criteria; we consider direct search optimization methods that do not require derivatives, as well as deterministic global optimization methods. Following this, we consider the solution of mixed-integer problems and outline the main characteristics of algorithms for their solution. Finally, we conclude with a discussion of optimization modeling software and its implementation in engineering models.

10.2. Gradient-Based Nonlinear Programming

For continuous variable optimization we consider problem 51 without discrete variables y.

The general NLP problem 52 is presented below:

$$\begin{aligned} &\text{Min} && f(x) \\ &\text{s.t.} && h(x) = 0 \\ & && g(x) \leq 0 \end{aligned} \tag{52}$$

and we assume that the functions $f(x)$, $h(x)$, and $g(x)$ have continuous first and second derivatives. A key characteristic of problem 52 is whether the problem is convex or not, i.e., whether it has a convex objective function and a convex feasible region. A function $\phi(x)$ of x in some domain X is convex if and only if for all points $x_1, x_2 \in X$:

$$\phi[\alpha x_1 + (1-\alpha) x_2] \leq \alpha\phi(x_1) + (1-\alpha)\phi(x_2) \tag{53}$$

holds for all $\alpha \in (0, 1)$. If $\phi(x)$ is differentiable, then an equivalent definition is:

$$\phi(x_1) + \nabla\phi(x_1)^T (x - x_1) \leq \phi(x) \tag{54}$$

Strict convexity requires that the inequalities 53 and 54 be strict. Convex feasible regions require $g(x)$ to be a convex function and $h(x)$ to be linear. If 52 is a convex problem, than any local solution is guaranteed to be a global solution to 52. Moreover, if the objective function is strictly convex, then this solution x^* is unique. On the other hand, nonconvex problems may have multiple local solutions, i.e., feasible solutions that minimize the objective function within some neighborhood about the solution.

We first consider methods that find only local solutions to nonconvex problems, as more difficult (and expensive) search procedures are required to find a global solution. Local methods are currently very efficient and have been developed to deal with very large NLPs. Moreover, by considering the structure of convex NLPs (including LPs and QPs), even more powerful methods can be applied. To study these methods, we first consider conditions for local optimality.

Local Optimality Conditions – A Kinematic Interpretation. Local optimality conditions are generally derived from gradient information from the objective and constraint functions. The proof follows by identifying a local minimum point that has no feasible descent direction. Invoking a theorem of the alternative (e.g., Farkas – Lemma) leads to the celebrated Karush – Kuhn – Tucker (KKT) conditions [169]. Instead of a formal development of these conditions, we present here a more intuitive, kinematic illustration. Consider the contour plot of the objective function $f(x)$ given in Figure 36 as a smooth valley in space of the variables x_1 and x_2. For the contour plot of this unconstrained problem, Min $f(x)$, consider a ball rolling in this valley to the lowest point of $f(x)$, denoted by x^*. This point is at least a local minimum and is defined by a point with zero gradient and at least nonnegative curvature in all (nonzero) directions p. We use the first derivative (gradient) vector $\nabla f(x)$ and second derivative (Hessian) matrix $\nabla_{xx} f(x)$ to state the necessary first- and second-order conditions for unconstrained optimality:

$$\nabla_x f(x^*) = 0 \quad p^T \nabla_{xx} f(x^*) p \geq 0 \quad \text{for all } p \neq 0 \tag{55}$$

These necessary conditions for local optimality can be strengthened to sufficient conditions by making the inequality in the relations 55 strict (i.e., positive curvature in all directions). Equivalently, the sufficient (necessary) curvature conditions can be stated as: $\nabla_{xx} f(x^*)$ has all positive (nonnegative) eigenvalues and is therefore defined as a positive (semi-)definite matrix.

Figure 36. Unconstrained minimum

Now consider the imposition of inequality $[g(x) \leq 0]$ and equality constraints $[h(x) = 0]$ in Figure 37. Continuing the kinematic interpretation, the inequality constraints $g(x) \leq 0$ act as "fences" in the valley, and equality constraints

$h(x) = 0$ as "rails". Consider now a ball, constrained on a rail and within fences, to roll to its lowest point. This stationary point occurs when the normal forces exerted by the fences $[-\nabla g(x^*)]$ and rails $[-\nabla h(x^*)]$ on the ball are balanced by the force of "gravity" $[-\nabla f(x^*)]$. This condition can be stated by the following *KKT necessary conditions* for constrained optimality:

Figure 37. Constrained minimum

Stationarity Condition: It is convenient to define the Lagrangian function $L(x, \lambda, \nu) = f(x) + g(x)^T\lambda + h(x)^T\nu$ along with "weights" or multipliers λ and ν for the constraints. These multipliers are also known as "dual variables" and "shadow prices". The stationarity condition (balance of forces acting on the ball) is then given by:

$$\nabla L(x,\lambda,\nu) = \nabla f(x) + \nabla h(x)\lambda + \nabla g(x)\nu = 0 \tag{56}$$

Feasibility: Both inequality and equality constraints must be satisfied (ball must lie on the rail and within the fences):

$$h(x) = 0, \quad g(x) \leq 0 \tag{57}$$

Complementarity: Inequality constraints are either strictly satisfied (active) or inactive, in which case they are irrelevant to the solution. In the latter case the corresponding KKT multiplier must be zero. This is written as:

$$\nu^T g(x) = 0, \quad \nu \geq 0 \tag{58}$$

Constraint Qualification: For a local optimum to satisfy the KKT conditions, an additional regularity condition or constraint qualification (CQ) is required. The KKT conditions are derived from gradient information, and the CQ can be viewed as a condition on the relative influence of constraint curvature. In fact, linearly constrained problems with nonempty feasible regions require no constraint qualification. On the other hand, as seen in Figure 38, the problem Min x_1, s.t. $x_2 \geq 0$, $(x_1)^3 \geq x_2$ has a minimum point at the origin but does not satisfy the KKT conditions because it does not satisfy a CQ.

Figure 38. Failure of KKT conditions at constrained minimum (note linear dependence of constraint gradients)

CQs be defined in several ways. For instance, the linear independence constraint qualification (LICQ) requires that the active constraints at x^* be linearly independent, i.e., the matrix $[\nabla h(x^*) \,|\, \nabla g_A(x^*)]$ is full column rank, where g_A is the vector of inequality constraints with elements that satisfy $g_{A,i}(x^*) = 0$. With LICQ, the KKT multipliers (λ, ν) are guaranteed to be unique at the optimal solution. The weaker Mangasarian – Fromovitz constraint qualification (MFCQ) requires only that $\nabla h(x^*)$ have full column rank and that a direction p exist that satisfies $\nabla h(x^*)^T p = 0$ and $\nabla g_A(x^*)^T p > 0$. With MFCQ, the KKT multipliers (λ, ν) are guaranteed to be bounded (but not necessarily unique) at the optimal solution. Additional discussion can be found in [169].

Second Order Conditions: As with unconstrained optimization, nonnegative (positive) curvature is necessary (sufficient) in all of the allowable (i.e., constrained) nonzero directions p. This condition can be stated in several ways. A typical necessary second-order condition requires a point x^* that satisfies LICQ and first-order conditions 56–58 with multipliers (λ, ν) to satisfy the additional conditions given by:

$$p^T \nabla_{xx} L(x^*,\lambda,\nu)p \geq 0 \quad \text{for all}$$
$$p \neq 0, \nabla h(x^*)^T p = 0,$$
$$\nabla g_A(x^*)^T p = 0 \tag{59}$$

The corresponding sufficient conditions require that the inequality in 59 be strict. Note that for the example in Figure 36, the allowable directions p span the entire space for x while in Figure 37, there are *no* allowable directions p.

Example: To illustrate the KKT conditions, consider the following unconstrained NLP:

$$\begin{aligned} &\text{Min } (x_1)^2 - 4x_1 + 3/2(x_2)^2 \\ &-7x_2 + x_1x_2 + 9 - \ln x_1 - \ln x_2 \end{aligned} \tag{60}$$

corresponding to the contour plot in Figure 36. The optimal solution can be found by solving for the first order conditions 54:

$$\nabla f(x) = \begin{bmatrix} 2x_1 - 4 + x_2 - 1/x_1 \\ 3x_2 - 7 + x_1 - 1/x_2 \end{bmatrix} = 0$$
$$\Rightarrow x^* = \begin{bmatrix} 1.3475 \\ 2.0470 \end{bmatrix} \tag{61}$$

and $f(x^*) = -2.8742$. Checking the second-order conditions leads to:

$$\nabla_{xx} f(x*) = \begin{bmatrix} 2 + 1/(x_1^*)^2 & 1 \\ 1 & 3 + 1/(x_2^*)^2 \end{bmatrix} \Rightarrow$$
$$\nabla_{xx} f(x*) = \begin{bmatrix} 2.5507 & 1 \\ 1 & 3.2387 \end{bmatrix} \text{(positive definite)} \tag{62}$$

Now consider the constrained NLP:

$$\begin{aligned} \text{Min} \quad & (x_1)^2 - 4x_1 + 3/2(x_1)^2 - 7x_2 + x_1x_2 \\ & + 9 - \ln x_1 - \ln x_2 \\ \text{s.t.} \quad & 4 - x_1x_2 \leq 0 \\ & 2x_1 - x_2 = 0 \end{aligned} \tag{63}$$

that corresponds to the plot in Figure 37. The optimal solution can be found by applying the first-order KKT conditions 56–58:

$$\nabla L(x,\lambda,\nu) = \nabla f(x) + \nabla h(x)\lambda + \nabla g(x)\nu =$$
$$\begin{bmatrix} 2x_1 - 4 + x_2 - 1/x_1 \\ 3x_2 - 7 + x_1 - 1/x_2 \end{bmatrix} + \begin{bmatrix} 2 \\ -1 \end{bmatrix} \lambda + \begin{bmatrix} -x_2 \\ -x_1 \end{bmatrix} \nu = 0$$
$$g(x) = 4 - x_1x_2 \leq 0, \quad h(x) = 2x_1 - x_2 = 0$$
$$g(x)\nu = (4 - x_1x_2)\nu, \quad \nu \geq 0$$
$$\Downarrow$$
$$x* = \begin{bmatrix} 1.4142 \\ 2.8284 \end{bmatrix}, \lambda* = 1.036, \nu* = 1.068$$

and $f(x^*) = -1.8421$. Checking the second-order conditions 59 leads to:

$$\nabla_{xx} L(x*,\lambda*,\nu*) = \nabla_{xx}[f(x*) + h(x*)\lambda* + g(x*)\nu*] =$$
$$\begin{bmatrix} 2 + 1/(x_1)^2 & 1 - \nu \\ 1 - \nu & 3 + 1/(x_2)^2 \end{bmatrix} = \begin{bmatrix} 2.5 & 0.068 \\ 0.068 & 3.125 \end{bmatrix}$$
$$[\nabla h(x*) | \nabla g_A(x*)]$$
$$p = \begin{bmatrix} 2 & -2.8284 \\ -1 & -1.4142 \end{bmatrix} p = 0, p \neq 0$$

Note that LICQ is satisfied. Moreover, because $[\nabla h(x^*) | \nabla g_A(x^*)]$ is square and nonsingular, there are no nonzero vectors p that satisfy the allowable directions. Hence, the sufficient second-order conditions ($p^T \nabla_{xx} L(x^*,\lambda^*,\nu^*) > 0$, for all allowable p) are *vacuously satisfied* for this problem.

Convex Cases of NLP. Linear programs and quadratic programs are special cases of problem 52 that allow for more efficient solution, based on application of KKT conditions 56–59. Because these are convex problems, any locally optimal solution is a global solution. In particular, if the objective and constraint functions in problem 52 are linear then the following linear program (LP):

$$\begin{aligned} \text{Min} \quad & c^T x \\ \text{s.t.} \quad & Ax = b \\ & Cx \leq d \end{aligned} \tag{65}$$

can be solved in a finite number of steps, and the optimal solution lies at a vertex of the polyhedron described by the linear constraints. This is shown in Figure 39, and in so-called primal degenerate cases, multiple vertices can be alternate optimal solutions with the same values of the objective function. The standard method to solve problem 65 is the simplex method, developed in the late 1940s [170], although, starting from KARMARKAR's discovery in 1984, interior point methods have become quite advanced and competitive for large scale problems [171]. The simplex method proceeds by moving successively from vertex to vertex with improved objective function values. Methods to solve problem 65 are well implemented and widely used,

especially in planning and logistical applications. They also form the basis for MILP methods (see below). Currently, state-of-the-art LP solvers can handle millions of variables and constraints and the application of further decomposition methods leads to the solution of problems that are two or three orders of magnitude larger than this [172, 173]. Also, the interior point method is described below from the perspective of more general NLPs.

Figure 39. Contour plots of linear programs

Quadratic programs (QP) represent a slight modification of problem 65 and can be stated as:

$$\begin{array}{ll} \text{Min} & c^T x + \frac{1}{2} x^T Q x \\ \text{s.t.} & Ax = b \\ & x \leq d \end{array} \tag{66}$$

If the matrix Q is positive semidefinite (positive definite), when projected into the null space of the active constraints, then problem 66 is (strictly) convex and the QP is a global (and unique) minimum. Otherwise, local solutions exist for problem 66, and more extensive global optimization methods are needed to obtain the global solution. Like LPs, convex QPs can be solved in a finite number of steps. However, as seen in Figure 40, these optimal solutions can lie on a vertex, on a constraint boundary, or in the interior. A number of active set strategies have been created that solve the KKT conditions of the QP and incorporate efficient updates of active constraints. Popular QP methods include null space algorithms, range space methods, and Schur complement methods. As with LPs, QP problems can also be solved with interior point methods [171].

Figure 40. Contour plots of convex quadratic programs

Solving the General NLP Problem. Solution techniques for problem 52 deal with satisfaction of the KKT conditions 56–59. Many NLP solvers are based on successive quadratic programming (SQP) as it allows the construction of a number of NLP algorithms based on the Newton – Raphson method for equation solving. SQP solvers have been shown to require the fewest function evaluations to solve NLPs [174] and they can be tailored to a broad range of process engineering problems with different structure.

The SQP strategy applies the equivalent of a Newton step to the KKT conditions of the nonlinear programming problem, and this leads to a fast rate of convergence. By adding slack variables s the first-order KKT conditions can be rewritten as:

$$\nabla f(x)+\nabla h(x)\lambda+\nabla g(x)\nu=0 \tag{67a}$$

$$h(x)=0 \tag{67b}$$

$$g(x)+s=0 \tag{67c}$$

$$SVe=0 \tag{67d}$$

$$(s,\nu)\geq 0 \tag{67e}$$

where $e=[1,\ 1,\ \ldots,\ 1]^T$, $S=\mathrm{diag}(s)$ and $V=\mathrm{diag}(\nu)$. SQP methods find solutions that satisfy Equations 67a, 67b, 67c, 67d and 67e by generating Newton-like search directions at iteration k. However, equations 67d and active bounds 67e are dependent and serve to make the KKT system ill-conditioned near the solution. SQP algorithms treat these conditions in two ways. In the *active set strategy*, discrete decisions are made regarding the active constraint set, $i\in I=\{i|g_i(x^*)=0\}$, and Equation 67d is replaced by $s_i=0$, $i\in I$, and $v_i=0$, $i\notin I$. Determining the active set is a combinatorial problem, and a straightforward way to determine an estimate of the active set [and also satisfy 67e] is to formulate, at a point x^k, and solve the following QP at iteration k:

$$\begin{array}{ll} \text{Min} & \nabla f(x^k)^T p+\frac{1}{2}p^T\nabla_{xx}L(x^k,\lambda^k,\nu^k)\,p \\ \text{s.t.} & h(x^k)+\nabla h(x^k)^T p=0 \\ & g(x^k)+\nabla g(x^k)^T p+s=0,\ s\geq 0 \end{array} \tag{68}$$

The KKT conditions of 68 are given by:

$$\nabla f\left(x^k\right)+\nabla^2 L\left(x^k,\lambda^k,\nu^k\right)p$$
$$+\nabla h\left(x^k\right)\lambda+\nabla g\left(x^k\right)\nu=0 \tag{69a}$$

$$h\left(x^k\right)+\nabla h\left(x^k\right)^T p=0 \tag{69b}$$

$$g\left(x^k\right)+\nabla g\left(x^k\right)^T p+s=0 \tag{69c}$$

$$SVe=0 \tag{69d}$$

$$(s,\nu)\geq 0 \tag{69e}$$

where the Hessian of the Lagrange function $\nabla_{xx}L(x,\lambda,\nu)=\nabla_{xx}\left[f(x)+h(x)^T\lambda+g(x)^T\nu\right]$ is calculated directly or through a quasi-Newtonian approximation (created by differences of gradient vectors). It is easy to show that 69a–69c correspond to a Newton–Raphson step for 67a–67c applied at iteration k. Also, selection of the active set is now handled at the QP level by satisfying the conditions 69d, 69e. To evaluate and change candidate active sets, QP algorithms apply inexpensive matrix-updating strategies to the KKT matrix associated with the QP 68. Details of this approach can be found in [175, 176].

As alternatives that avoid the combinatorial problem of selecting the active set, interior point (or barrier) methods modify the NLP problem 52 to form problem 70

$$\begin{array}{ll} \text{Min} & f\left(x^k\right)-\mu\sum_i \ln s_i \\ \text{s.t.} & h\left(x^k\right)=0 \\ & g\left(x^k\right)+s=0 \end{array} \tag{70}$$

where the solution to this problem has $s>0$ for the penalty parameter $\mu>0$, and decreasing μ to zero leads to solution of problem 52. The KKT conditions for this problem can be written as Equation 71

$$\begin{array}{l} \nabla f(x*)+\nabla h(x*)\lambda+\nabla g(x*)\nu=0 \\ h(x*)=0 \\ g(x*)+s=0 \\ SVe=\mu e \end{array} \tag{71}$$

and at iteration k the Newton steps to solve 71 are given by:

$$\begin{bmatrix} \nabla_{xx}L(x_k,\lambda_k,\nu_k) & & \nabla h(x_k) & \nabla g(x_k) \\ & S_k^{-1}V_k & & I \\ \nabla h(x_k)^T & & & \\ \nabla g(x_k)^T & I & & \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta s \\ \Delta\lambda \\ \Delta\nu \end{bmatrix} = -\begin{bmatrix} \nabla_x L(x_k,\lambda_k,\nu_k) \\ \nu_k-S_k^{-1}\mu e \\ h(x_k) \\ g(x_k)+s_k \end{bmatrix} \tag{72}$$

A detailed description of this algorithm, called IPOPT, can be found in [177].

Both active set and interior point methods have clear trade-offs. Interior point methods may require more iterations to solve problem 70 for various values of μ, while active set methods require the solution of the more expensive QP subproblem 68. Thus, if there are few inequality constraints or an active set is known (say from a good starting guess, or a known QP solution from a previous iteration) then solving problem 68 is not expensive and the active set method is favored. On the other hand, for problems with

many inequality constraints, interior point methods are often faster as they avoid the combinatorial problem of selecting the active set. This is especially the case for large-scale problems and when a large number of bounds are active. Examples that demonstrate the performance of these approaches include the solution of model predictive control (MPC) problems [178 – 180] and the solution of large optimal control problems using barrier NLP solvers. For instance, IPOPT allows the solution of problems with more than 10^6 variables and up to 50 000 degrees of freedom [181, 182].

Other Gradient-Based NLP Solvers. In addition to SQP methods, a number of NLP solvers have been developed and adapted for large-scale problems. Generally, these methods require more function evaluations than SQP methods, but they perform very well when interfaced to optimization modeling platforms, where function evaluations are cheap. All of these can be derived from the perspective of applying Newton steps to portions of the KKT conditions.

LANCELOT [183] is based on the solution of bound constrained subproblems. Here an augmented Lagrangian is formed from problem 52 and subproblem 73 is solved.

$$\begin{aligned} &\text{Min } f(x)+\lambda^T h(x) \\ &\quad +\nu(g(x)+s)+\tfrac{1}{2}\rho\|g(x),g(x)+s\|^2 \\ &\text{s.t.} \quad s\geq 0 \end{aligned} \tag{73}$$

The above subproblem can be solved very efficiently for fixed values of the multipliers λ and v and penalty parameter ρ. Here a gradient-projection, trust-region method is applied. Once subproblem 73 is solved, the multipliers and penalty parameter are updated in an outer loop and the cycle repeats until the KKT conditions for problem 52 are satisfied. LANCELOT works best when exact second derivatives are available. This promotes a fast convergence rate in solving each subproblem and allows a bound constrained trust-region method to exploit directions of negative curvature in the Hessian matrix.

Reduced gradient methods are active set strategies that rely on partitioning the variables and solving Equations 67a, 67b, 67c, 67d and 67e in a nested manner. Without loss of generality, problem 52 can be rewritten as problem 74.

$$\begin{aligned} &\text{Min } f(z) \\ &\text{s.t. } c(z)=0 \\ &a\leq z\leq b \end{aligned} \tag{74}$$

Variables are partitioned as nonbasic variables (those fixed to their bounds), basic variables (those that can be solved from the equality constraints), and superbasic variables (those remaining variables between bounds that serve to drive the optimization); this leads to $z^T=\left[z_N^T,z_S^T,z_B^T\right]$. This partition is derived from local information and may change over the course of the optimization iterations. The corresponding KKT conditions can be written as Equations 75a, 75b, 75c, 75d and 75e

$$\nabla_{\mathrm{N}} f(z)+\nabla_{\mathrm{N}} c(z)\gamma=\beta_{\mathrm{a}}-\beta_{\mathrm{b}} \tag{75a}$$

$$\nabla_{\mathrm{S}} f(z)+\nabla_{\mathrm{S}} c(z)\gamma=0 \tag{75b}$$

$$\nabla_{\mathrm{B}} f(z)+\nabla_{\mathrm{B}} c(z)\gamma=0 \tag{75c}$$

$$c(z)=0 \tag{75d}$$

$$z_{\mathrm{N},j}=a_j \text{ or } b_j,\ \beta_{\mathrm{a},j}\geq 0,\beta_{\mathrm{b},j}=0 \text{ or } \beta_{\mathrm{b},j}\geq 0,\beta_{\mathrm{a},j}=0 \tag{75e}$$

where λ and β are the KKT multipliers for the equality and bound constraints, respectively, and 75e replaces the complementarity conditions 58. Reduced gradient methods work by nesting equations 75b, 75d within 75a, 75c. At iteration k, for fixed values of z_{N}^k and z_{S}^k, we can solve for z_{B} using 75d and for λ using 75b. Moreover, linearization of these equations leads to constrained derivatives or *reduced gradients* (Eq. 76)

$$\frac{df}{dz_{\mathrm{s}}}=\nabla f_{\mathrm{s}}-\nabla c_{\mathrm{s}}(\nabla c_{\mathrm{B}})^{-1}\nabla f_{\mathrm{B}} \tag{76}$$

which indicate how $f(z)$ (and z_{B}) change with respect to z_{S} and z_{N}. The algorithm then proceeds by updating z_{S} using reduced gradients in a Newton-type iteration to solve equation 75c. Following this, bound multipliers β are calculated from 75a. Over the course of the iterations, if the variables z_{B} or z_{S} exceed their bounds or if some bound multipliers β become negative, then the variable partition needs to be changed and the equations 75a, 75b, 75c, 75d and 75e are reconstructed. These reduced gradient methods are embodied in the popular GRG2, CONOPT, and SOLVER codes [173].

The SOLVER code has been incorporated into Microsoft Excel. CONOPT [184] is an efficient and widely used code in several optimization modeling environments.

MINOS [185] is a well-implemented package that offers a variation on reduced gradient strategies. At iteration *k,* equation 75d is replaced by its linearization (Eq. 77)

$$c(z_{\mathrm{N}}^k, z_{\mathrm{S}}^k, z_{\mathrm{B}}^k) + \nabla_{\mathrm{B}} c\left(z^k\right)^T (z_{\mathrm{B}} - z_{\mathrm{B}}^k) + \nabla_{\mathrm{S}} c\left(z^k\right)^T (z_{\mathrm{S}} - z_{\mathrm{S}}^k) = 0 \quad (77)$$

and (75a–75c, 75e) are solved with Equation 77 as a subproblem using concepts from the reduced gradient method. At the solution of this subproblem, the constraints 75d are relinearized and the cycle repeats until the KKT conditions of 75a, 75b, 75c, 75d and 75e are satisfied. The augmented Lagrangian function 73 is used to penalize movement away from the feasible region. For problems with few degrees of freedom, the resulting approach leads to an extremely efficient method even for very large problems. MINOS has been interfaced to a number of modeling systems and enjoys widespread use. It performs especially well on large problems with few nonlinear constraints. However, on highly nonlinear problems it is usually less reliable than other reduced gradient methods.

Algorithmic Details for NLP Methods. All of the above NLP methods incorporate concepts from the Newton – Raphson Method for equation solving. Essential features of these methods are a) providing accurate derivative information to solve for the KKT conditions, b) stabilization strategies to promote convergence of the Newton-like method from poor starting points, and c) regularization of the Jacobian matrix in Newton's method (the so-called KKT matrix) if it becomes singular or ill-conditioned.

a) *Providing first and second derivatives:* The KKT conditions require first derivatives to define stationary points, so accurate first derivatives are essential to determine locally optimal solutions for differentiable NLPs. Moreover, Newton–Raphson methods that are applied to the KKT conditions, as well as the task of checking second-order KKT conditions, necessarily require information on second derivatives. (Note that second-order conditions are not checked by methods that do not use second derivatives). With the recent development of automatic differentiation tools, many modeling and simulation platforms can provide exact first and second derivatives for optimization. When second derivatives are available for the objective or constraint functions, they can be used directly in LANCELOT, SQP and, less efficiently, in reduced gradient methods. Otherwise, for problems with few superbasic variables, reduced gradient methods and reduced space variants of SQP can be applied. Referring to problem 74 with *n* variables and *m* equalities, we can write the QP step from problem 68 as Equation 78.

$$\begin{aligned} \text{Min} \quad & \nabla f\left(z^k\right)^T p + {}^1\!/_2\, p^T \nabla_{xx} L\left(z^k, \gamma^k\right) p \\ \text{s.t.} \quad & c\left(z^k\right) + \nabla c\left(z^k\right)^T p = 0 \\ & a \le z^k + p \le b \end{aligned} \quad (78)$$

Defining the search direction as $p = Z_k p_Z + Y_k p_Y$, where $\nabla c(x^k)^T Z_k = 0$ and $[Y_k | Z_k]$ is a nonsingular $n \times n$ matrix, allows us to form the following reduced QP subproblem (with $n-m$ variables)

$$\begin{aligned} \text{Min} \quad & \left[Z_k^T \nabla f\left(z^k\right) + w_k\right]^T p_Z + \tfrac{1}{2} p z^T B_k p_Z \\ \text{s.t.} \quad & a \le z^k + Z_k p_Z + Y_k p_Y \le b \end{aligned} \quad (79)$$

where $p_Y = -[\nabla c(z^k)^T Y_k]^{-1} c(z^k)$. Good choices of Y_k and Z_k, which allow sparsity to be exploited in $\nabla c(z^k)$, are: $Y_k^T = [0|I]$ and $Z_k^T = \left[I | -\nabla_{\mathrm{N,S}} c\left(z^k\right) \nabla_B c\left(z^k\right)^{-1}\right]$. Here we define the reduced Hessian $B_k = Z_z^T \nabla_{zz} L\left(z^k, \gamma^k\right) Z_k$ and $w_k = Z_k^T \nabla_{zz} L\left(z^k, \gamma^k\right) Y_k p_Y$. In the absence of second-derivative information, B_k can be approximated using positive definite quasi-Newton approximations [175]. Also, for the interior point method, a similar reduced space decomposition can be applied to the Newton step given in 72.

Finally, for problems with least-squares functions, as in data reconciliation, parameter estimation, and model predictive control, one can often assume that the values of the objective function and its gradient at the solution are vanishingly small. Under these conditions, one can show that the multipliers (λ, ν) also vanish and $\nabla_{xx} L(x^*, \lambda, \nu)$ can be substituted

by $\nabla_{xx} f(x^*)$. This *Gauss – Newton approximation* has been shown to be very efficient for the solution of least-squares problems [175].

b) *Line-search and trust-region methods* are used to promote convergence from poor starting points. These are commonly used with the search directions calculated from NLP subproblems such as problem 68. In a *trust-region approach*, the constraint, $\|p\| \leq \Delta$ is added and the iteration step is taken if there is sufficient reduction of some merit function (e.g., the objective function weighted with some measure of the constraint violations). The size of the trust region Δ is adjusted based on the agreement of the reduction of the actual merit function compared to its predicted reduction from the subproblem [183]. Such methods have strong global convergence properties and are especially appropriate for ill-conditioned NLPs. This approach has been applied in the KNITRO code [186]. *Line-search methods* can be more efficient on problems with reasonably good starting points and well-conditioned subproblems, as in real-time optimization. Typically, once a search direction is calculated from problem 68, or other related subproblem, a step size $\alpha \in (0, 1]$ is chosen so that $x^k + \alpha p$ leads to a sufficient decrease of a merit function. As a recent alternative, a novel *filter-stabilization* strategy (for both line-search and trust-region approaches) has been developed based on a bicriterion minimization, with the objective function and constraint infeasibility as competing objectives [187]. This method often leads to better performance than those based on merit functions.

c) *Regularization of the KKT matrix for the NLP subproblem* (e.g., in Equation 72) is essential for good performance of general purpose algorithms. For instance, to obtain a unique solution to Eqn. 72, active constraint gradients must be full rank, and the Hessian matrix, when projected into the null space of the active constraint gradients, must be positive definite. These properties may not hold far from the solution, and corrections to the Hessian in SQP may be necessary [176]. Regularization methods ensure that subproblems like Eqns. 68 and 72 remain well-conditioned; they include addition of positive constants to the diagonal of the Hessian matrix to ensure its positive definiteness, judicious selection of active constraint gradients to ensure that they are linearly independent, and scaling the subproblem to reduce the propagation of numerical errors. Often these strategies are heuristics built into particular NLP codes. While quite effective, most of these heuristics do not provide convergence guarantees for general NLPs.

Table 11 summarizes the characteristics of a collection of widely used NLP codes. Much more information on widely available codes can also be found on the NEOS server (www-neos.mcs.anl.gov) and the NEOS Software Guide.

Table 11. Representative NLP solvers

Method	Algorithm type	Stabilization	Second-order information
CONOPT [184]	reduced gradient	line search	exact and quasi-Newton
GRG2 [173]	reduced gradient	line search	quasi-Newton
IPOPT [177]	SQP, barrier	line search	exact
KNITRO [186]	SQP, barrier	trust region	exact and quasi-Newton
LANCELOT [183]	aug mented Lagrangian, bound constrained	trust region	exact and quasi-Newton
LOQO [188]	SQP, barrier	line search	exact
MINOS [185]	reduced gradient, augmented Lagrangian	line search	quasi-Newton
NPSOL [189]	SQP, Active set	line search	quasi-Newton
SNOPT [190]	reduced space SQP, active set	line search	quasi-Newton
SOCS [191]	SQP, active set	line search	exact
SOLVER [173]	reduced gradient	line search	quasi-Newton
SRQP [192]	reduced space SQP, active set	line search	quasi-Newton

10.3. Optimization Methods without Derivatives

A broad class of optimization strategies does not require derivative information. These methods have the advantage of easy implementation and little prior knowledge of the optimization problem. In particular, such methods are well suited for "quick and dirty" optimization studies that explore the scope of optimization for new problems, prior to investing effort for more sophisticated modeling and solution strategies. Most of these methods are derived from heuristics that naturally spawn numerous variations. As a result, a very broad literature describes these methods. Here we discuss only a few important trends in this area.

Classical Direct Search Methods. Developed in the 1960s and 1970s, these methods include one-at-a-time search and methods based on experimental designs [193]. At that time, these direct search methods were the most popular optimization methods in chemical engineering. Methods that fall into this class include the pattern search [194], the conjugate direction method [195], simplex and complex searches [196], and the adaptive random search methods [197 – 199]. All of these methods require only objective function values for unconstrained minimization. Associated with these methods are numerous studies on a wide range of process problems. Moreover, many of these methods include heuristics that prevent premature termination (e.g., directional flexibility in the complex search as well as random restarts and direction generation). To illustrate these methods, Figure 41 illustrates the performance of a pattern search method as well as a random search method on an unconstrained problem.

Simulated Annealing. This strategy is related to random search methods and derives from a class of heuristics with analogies to the motion of molecules in the cooling and solidification of metals [200]. Here a "temperature" parameter θ can be raised or lowered to influence the probability of accepting points that do not improve the objective function. The method starts with a base point x and objective value $f(x)$. The next point x' is chosen at random from a distribution. If $f(x') < f(x)$, the move is accepted with x' as the new point. Otherwise, x' is accepted with probability $p(\theta,x',x)$. Options include the Metropolis distribution, $p(\theta,x,x') = \exp[-\{f(x')-f(x)\}/\theta]$, and the Glauber distribution, $p(\theta, x, x') = \exp[-\{f(x')-f(x)\}/(1 + \exp[-\{f(x')-f(x)\}]/\theta)]$. The θ parameter is then reduced and the method continues until no further progress is made.

Genetic Algorithms. This approach, first proposed in [201], is based on the analogy of improving a population of solutions through modifying their gene pool. It also has similar performance characteristics as random search methods and simulated annealing. Two forms of ge-

netic modification, crossover or mutation, are used and the elements of the optimization vector $\boldsymbol{x}$ are represented as binary strings. Crossover deals with random swapping of vector elements (among parents with highest objective function values or other rankings of population) or any linear combinations of two parents. Mutation deals with the addition of a random variable to elements of the vector. Genetic algorithms (GAs) have seen widespread use in process engineering and a number of codes are available. A related GA algorithm is described in [173].

Derivative-Free Optimization (DFO). In the past decade, the availability of parallel computers and faster computing hardware and the need to incorporate complex simulation models within optimization studies have led a number of optimization researchers to reconsider classical direct search approaches. In particular, Dennis and Torczon [202] developed a multidimensional search algorithm that extends the simplex approach [196]. They note that the Nelder–Mead algorithm fails as the number of variables increases, even for very simple problems. To overcome this, their multidimensional pattern-search approach combines reflection, expansion, and contraction steps that act as line search algorithms for a number of linear independent search directions. This approach is easily adapted to parallel computation and the method can be tailored to the number of processors available. Moreover, this approach converges to locally optimal solutions for unconstrained problems and exhibits an unexpected performance synergy when multiple processors are used. The work of Dennis and Torczon [202] has spawned considerable research on analysis and code development for DFO methods. Moreover, Conn et al. [203] construct a multivariable DFO algorithm that uses a surrogate model for the objective function within a trust-region method. Here points are sampled to obtain a well-defined quadratic interpolation model, and descent conditions from trust-region methods enforce convergence properties. A number of trust-region methods that rely on this approach are reviewed in [203]. Moreover, a number of DFO codes have been developed that lead to black-box optimization implementations for large, complex simulation models. These include the DAKOTA package at Sandia National Lab [204], http://endo.sandia.gov/DAKOTA/software.html and FOCUS developed at Boeing Corporation [205].

Direct search methods are easy to apply to a wide variety of problem types and optimization models. Moreover, because their termination criteria are not based on gradient information and stationary points, they are more likely to favor the search for global rather than locally optimal solutions. These methods can also be adapted easily to include integer variables. However, rigorous convergence properties to globally optimal solutions have not yet been discovered. Also, these methods are best suited for unconstrained problems or for problems with simple bounds. Otherwise, they may have difficulties with constraints, as the only options open for handling constraints are equality constraint elimination and addition of penalty functions for inequality constraints. Both approaches can be unreliable and may lead to failure of the optimization algorithm. Finally, the performance of direct search methods scales poorly (and often exponentially) with the number of decision variables. While performance can be improved with the use of parallel computing, these methods are rarely applied to problems with more than a few dozen decision variables.

10.4. Global Optimization

Deterministic optimization methods are available for nonconvex nonlinear programming problems of the form problem 52 that guarantee convergence to the global optimum. More specifically, one can show under mild conditions that they converge to an ε distance to the global optimum on a finite number of steps. These methods are generally more expensive than local NLP methods, and they require the exploitation of the structure of the nonlinear program.

Global optimization of nonconvex programs has received increased attention due to their practical importance. Most of the deterministic global optimization algorithms are based on spatial branch-and-bound algorithm [206], which divides the feasible region of continuous variables and compares lower bound and upper bound for fathoming each subregion. The one that contains the optimal solution is found by eliminating subregions that are proved not to contain the optimal solution.

For nonconvex NLP problems, Quesada and Grossmann [207] proposed a spatial branch-and-bound algorithm for concave separable, linear fractional, and bilinear programs using linear and nonlinear underestimating functions [208]. For nonconvex MINLP, Ryoo and Sahinidis [209] and later Tawarmalani and Sahinidis [210] developed BARON, which branches on the continuous and discrete variables with bounds reduction method. Adjiman et al. [211, 212] proposed the SMIN-αBB and GMIN-αBB algorithms for twice-differentiable nonconvex MINLPs. Using a valid convex underestimation of general functions as well as for special functions, Adjiman et al. [213] developed the αBB method, which branches on both the continuous and discrete variables according to specific options. The branch-and-contract method [214] has bilinear, linear fractional, and concave separable functions in the continuous variables and binary variables, uses bound contraction, and applies the outer-approximation (OA) algorithm at each node of the tree. Smith and Pantelides [215] proposed a reformulation method combined with a spatial branch-and-bound algorithm for nonconvex MINLP and NLP.

Figure 42. Convex underestimator for nonconvex function

Because in global optimization one cannot exploit optimality conditions like the KKT conditions for a local optimum, these methods work by first partitioning the problem domain (i.e., containing the feasible region) into subregions (see Fig. 42). Upper bounds on the objective function are computed over all subregions of the problem. In addition, lower bounds can be derived from convex underestimators of the objective function and constraints for each subregion. The algorithm then proceeds to eliminate all subregions that have lower bounds that are greater than the least upper bound. After this, the remaining regions are further partitioned to create new subregions and the cycle continues until the upper and lower bounds converge. Below we illustrate the specific steps of the algorithm for nonlinear programs that involve bilinear, linear fractional, and concave separable terms [207, 214].

Nonconvex NLP with Bilinear, Linear Fractional, and Concave Separable Terms. Consider the following specific nonconvex NLP problem,

$$\underset{x}{\text{Min}} \quad f(x) = \sum_{(i,j)\in BL_0} a_{ij}\, x_i x_j + \sum_{(i,j)\in LF_0} b_{ij} \frac{x_i}{x_j} + \sum_{i\in C_0} g_i(x_i) + h(x)$$

subject to

$$f_k(x) = \sum_{(i,j)\in BL_k} a_{ijk} x_i x_j + \sum_{(i,j)\in LF_k} b_{ijk} \frac{x_i}{x_j} + \sum_{i\in C_k} g_{i,k}(x_i) + h_k(x) \le 0 \quad k\in K$$

$$x\in S\cap \Omega_0 \subset R^n$$

where a_{ij}, a_{ijk}, b_{ij}, b_{ijk} are scalars with $i\in I=\{1,2,\cdots,n\}$, $j\in J=\{1,2,\cdots,n\}$, and $k\in K=\{1,2,\cdots,m\}$. BL_0, BL_k, LF_0, LF_k are (i, j)-index sets, with $i\neq j$, that define the bilinear and linear fractional terms present in the problem. The functions $h(x)$, $h_k(x)$ are convex, and twice continuously differentiable. C_0 and C_k are index sets for the univariate twice continuously differentiable concave functions $g_i(x_i)$, $g_{i,k}(x_i)$. The set $S\subset R^n$ is convex, and $\omega_0 \supset R^n$ is an n-dimensional hyperrectangle defined in terms of the initial variable bounds $x^{\mathrm{L,in}}$ and $x^{\mathrm{U,in}}$:

$$\Omega_0 = \{x\in R^n : 0 \le x^{\mathrm{L,in}} \le x \le x^{\mathrm{U,in}},\ x_j^{\mathrm{L,in}} > 0 \text{ if } (i,j)\in LF_0 \cup LF_k,\quad i\in I, j\in J, k\in K\}$$

The feasible region of problem 80 is denoted by D. Note that a nonlinear equality constraint of the form $f_k(x) = 0$ can be accommodated in

problem 51 through the representation by the inequalities $f_k(x) \leq 0$ and $-f_k(x) \leq 0$, provided $h_k(x)$ is separable.

To obtain a lower bound LB (Ω) for the global minimum of problem 80 over $D \cap \Omega$, where $\Omega = \{x \in R^n : x^{\mathrm{L}} \leq x \leq x^{\mathrm{U}}\} \subseteq \Omega_0$, the following problem is proposed:

$$\underset{(x,y,z)}{\text{Min}} \quad \hat{f}(x,y,z) = \sum_{(i,j)\in BL_0} a_{ij}\, y_{ij}$$
$$+ \sum_{(i,j)\in LF_0} b_{ij} z_{ij} + \sum_{i\in C_0} \hat{g}_i(x_i) + h(x)$$

subject to

$$\hat{f}_k(x,y,z) = \sum_{(i,j)\in BL_k} a_{ijk} y_{ij} + \sum_{(i,j)\in LF_k} b_{ijk} z_{ij}$$
$$+ \sum_{i\in C_k} \hat{g}_{i,k}(x_i) + h_k(x) \leq 0 \quad k \in K$$
$$(x,y,z) \in T(\Omega) \subset R^n \times R^{n_1} \times R^{n_2}$$
$$x \in S \cap \Omega \subset R^n,\ y \in R_+^{n_1},\ z \in R_+^{n_2},$$

where the functions and sets are defined as follows:

a) $\hat{g}_i(x_i)$ and $\hat{g}_{i,k}(x_i)$ are the convex envelopes for the univariate functions over the domain $x_i \in [x_i^L, x_i^U]$ [216]:

$$\hat{g}_i(x_i) = g_i\left(x_i^{\mathrm{L}}\right) + \left(\frac{g_i\left(x_i^{\mathrm{U}}\right) - g_i\left(x_i^L\right)}{x_i^{\mathrm{U}} - x_i^{\mathrm{L}}}\right)\left(x_i - x_i^{\mathrm{L}}\right) \leq g_i(x_i) \tag{80}$$

$$\hat{g}_{i,k}(x_i) = g_{i,k}\left(x_i^{\mathrm{L}}\right) + \left(\frac{g_{i,k}\left(x_i^{\mathrm{U}}\right) - g_{i,k}\left(x_i^L\right)}{x_i^{\mathrm{U}} - x_i^{\mathrm{L}}}\right)\left(x_i - x_i^{\mathrm{L}}\right) \leq g_{i,k}(x_i) \tag{81}$$

where $\hat{g}_i(x_i) = g_i(x_i)$ at $x_i = x_i^{\mathrm{L}}$, and $x_i = x_i^{\mathrm{U}}$; likewise, $\hat{g}_{i,k}(x_i) = g_{i,k}(x_i)$ at $x_i = x_i^{\mathrm{L}}$, and $x_i = x_i^{\mathrm{U}}$.

b) $y = \{y_{ij}\}$ is a vector of additional variables for relaxing the bilinear terms in 80, and is used in the following inequalities which determine the convex and concave envelopes of bilinear terms:

$$\begin{aligned} y_{ij} &\geq x_j^{\mathrm{L}} x_i + x_i^{\mathrm{L}} x_j - x_i^{\mathrm{L}} x_j^{\mathrm{L}} && (i,j) \in BL^+ \\ y_{ij} &\geq x_j^{\mathrm{U}} x_i + x_i^{\mathrm{U}} x_j - x_i^{\mathrm{U}} x_j^{\mathrm{U}} && (i,j) \in BL^+ \end{aligned} \tag{82}$$

$$\begin{aligned} y_{ij} &\leq x_j^{\mathrm{L}} x_i + x_i^{\mathrm{U}} x_j - x_i^{\mathrm{U}} x_j^{\mathrm{L}} && (i,j) \in BL^- \\ y_{ij} &\leq x_j^{\mathrm{U}} x_i + x_i^{\mathrm{L}} x_j - x_i^{\mathrm{L}} x_j^{\mathrm{U}} && (i,j) \in BL^- \end{aligned} \tag{83}$$

where

$$BL^+ = \{(i,j) : (i,j) \in BL_0 \cup BL_k,\ a_{ij} > 0 \text{ or } a_{ijk} > 0,\ k \in K\}$$

$$BL^- = \{(i,j) : (i,j) \in BL_0 \cup BL_k,\ a_{ij} < 0 \text{ or } a_{ijk} < 0,\ k \in K\}$$

The inequalities 82 were first derived by McCormick [208], and along with the inequalities 83 theoretically characterized by Al-Khayyal and Falk [217, 218].

c) $z = \{z_{ij}\}$ is a vector of additional variables for relaxing the linear fractional terms in problem 80; these variables are used in the following inequalities:

$$\begin{aligned} z_{ij} &\geq \frac{x_i}{x_j^{\mathrm{L}}} + x_i^{\mathrm{U}}\left(\frac{1}{x_j} - \frac{1}{x_j^{\mathrm{L}}}\right) && (i,j) \in LF^+ \\ z_{ij} &\geq \frac{x_i}{x_j^{\mathrm{U}}} + x_i^{L}\left(\frac{1}{x_j} - \frac{1}{x_j^{\mathrm{U}}}\right) && (i,j) \in LF^+ \end{aligned} \tag{84}$$

$$z_{ij} \geq \frac{1}{x_j}\left(\frac{x_i + \sqrt{x_i^{\mathrm{L}} x_i^{\mathrm{U}}}}{\sqrt{x_i^{\mathrm{L}}} + \sqrt{x_i^{\mathrm{U}}}}\right)^2 \quad (i,j) \in LF^+ \tag{85}$$

$$\begin{aligned} z_{ij} &\leq \frac{1}{x_j^{\mathrm{L}} x_j^{\mathrm{U}}}\left(x_j^{\mathrm{U}} x_i - x_i^{\mathrm{L}} x_j + x_i^{\mathrm{L}} x_j^{\mathrm{L}}\right) && (i,j) \in LF^- \\ z_{ij} &\leq \frac{1}{x_j^{\mathrm{L}} x_j^{\mathrm{U}}}\left(x_j^{\mathrm{L}} x_i - x_i^{\mathrm{U}} x_j + x_i^{\mathrm{U}} x_j^{\mathrm{U}}\right) && (i,j) \in LF^- \end{aligned} \tag{86}$$

where

$$LF^+ = \{(i,j) : (i,j) \in LF_0 \cup LF_k,\ b_{ij} > 0 \text{ or } b_{ijk} > 0,\ k \in K\}$$

$$LF^- = \{(i,j) : (i,j) \in LF_0 \cup LF_k,\ b_{ij} < 0 \text{ or } b_{ijk} < 0,\ k \in K\}$$

The inequalities 84 and 85, 86 are convex underestimators due to Quesada and Grossmann [207, 219] and Zamora and Grossmann [214], respectively.

d) $T(\Omega) = \{(x,y,z) \in R^n \times R^{n_1} \times R^{n_2} :$ 80– 85 are satisfied with $x^{\mathrm{L}}, x^{\mathrm{U}}$ as in $\Omega\}$. The feasible region, and the solution of problem 52 are denoted by $M(\Omega)$, and $(\hat{x}, \hat{y}, \hat{z})_{\Omega}$, respectively. We define the *approximation gap* $\varepsilon(\Omega)$ at a branch-and-bound node as

$$\varepsilon(\Omega) = \begin{cases} \infty & \text{if OUB} = \infty \\ -\text{LB}(\Omega) & \text{if OUB} = 0 \\ \frac{(\text{OUB} - \text{LB}(\Omega))}{|\text{OUB}|} & \text{otherwise} \end{cases} \tag{87}$$

where the *overall upper bound* (OUB) is the value of $f(x)$ at the best available feasible point $x \in D$; if no feasible point is available, then OUB$=\infty$.

Note that the underestimating problem 80 is a linear program if $LF^{+}=\varnothing$. During the execution of the spatial branch-and-bound algorithm, problem (NBNC) is solved initially over $M(\Omega_0)$ (root node of the branch-and-bound tree). If a better approximation is required, $M(\Omega_0)$ is refined by partitioning Ω_0 into two smaller hyperrectangles Ω_{01} and Ω_{02}, and two children nodes are created with relaxed feasible regions given by $M(\Omega_{01})$ and $M(\Omega_{02})$. Problem 80 might be regarded as a basic underestimating program for the general problem 80. In some cases, however, it is possible to develop additional convex estimators that might strengthen the underestimating problem. See, for instance, the projections proposed by Quesada and Grossmann [207], the reformulation–linearization technique by Sherali and Alameddine [220], and the reformulation–convexification approach by Sherali and Tuncbilek [221].

The Set of Branching Variables. A set of branching variables, characterized by the index set BV (Ω) defined below, is determined by considering the optimal solution $(\hat{x},\hat{y},\hat{z})_{\Omega}$ of the underestimating problem:

$$\begin{aligned}&\mathrm{BV}(\Omega)=\{i,j\colon |\hat{y}_{ij}-\hat{x}_i\hat{x}_j|=\zeta_l \text{ or } |\hat{z}_{ij}-\hat{x}_i/\hat{x}_j|=\zeta_l\\ &\text{or } g_i(\hat{x}_i)-\hat{g}_i(\hat{x}_i)=\zeta_l \text{ or } g_{i,k}(\hat{x}_i)-\hat{g}_{i,k}(\hat{x}_i)=\zeta_l,\\ &\text{for } i\in I, j\in J, k\in K, l\in L\}\end{aligned} \tag{88}$$

where, for a prespecified number l_n, $L=\{1,2,\ldots,l_n\}$ and ζ_1 is the magnitude of the largest approximation error for a nonconvex term in problem 80 evaluated at $(\hat{x},\hat{y},\hat{z})_{\Omega}$:

$$\begin{aligned}&\xi_1=\mathrm{Max}\ [|\hat{y}_{ij}-\hat{x}_i\hat{x}_j|,\ |\hat{z}_{ij}-\hat{x}_i/\hat{x}_j|,\ g_i(\hat{x}_i)-\hat{g}_i(\hat{x}_i),\\ &g_{i,k}(\hat{x}_i)-\hat{g}_{i,k}(\hat{x}_i)]\\ &i\in I, j\in J, k\in K\end{aligned}$$

Similarly, we define $\xi_l<\xi_{l-1}$ with $l\in L\setminus\{1\}$ as the l-th largest magnitude for an approximation error; for instance, $\xi_2<\xi_1$ is the second largest magnitude for an approximation error. Note that in some cases it might be convenient to introduce weights in the determination of BV (Ω) in order to scale differences in the approximation errors or to induce preferential branching schemes. This might be particularly useful in applications where specific information can be exploited by imposing an order of precedence on the set of complicating variables.

This basic concept in spatial branch-and-bound for global optimization is as follows. *Bounds* are related to the calculation of upper and lower bounds. For the former, any feasible point or, preferably, a locally optimal point in the subregion, can be used. For the lower bound, convex relaxations of the objective and constraint function are derived such as in problem 80. The *refining* step deals with the construction of partitions in the domain and further partitioning them during the search process. Finally, the *selection* step decides on the order of exploring the open subregions. Thus, the feasible region and the objective function are replaced by convex envelopes to form relaxed problems. Solving these convex relaxed problems leads to global solutions that are lower bounds to the NLP in the particular subregion. Finally, we see that gradient-based NLP solvers play an important role in global optimization algorithms, as they often yield the lower and upper bounds for the subregions. The following *spatial branch-and-bound* global optimization algorithm can therefore be given by the following steps:

0. Initialize algorithm: calculate upper bound by obtaining a local solution to problem 80. Calculate a lower bound solving problem 80 over the entire (relaxed) feasible region Ω_0.

For iteration k with a set of partitions $\Omega_{k,j}$ and bounds in each subregion OLB_j and OUB_j:

1) *Bound:* Define best upper bound: OUB = Min_j OUB_j and delete (fathom) all subregions j with lower bounds $\mathrm{OLB}_j \geq \mathrm{OUB}-\varepsilon$, stop.
2) *Refine:* Divide the remaining active subregions into partitiions $\Omega_{k,j1}$ and $\Omega_{k,j2}$. (Several branching rules are available for this step.)
3) *Select:* Solve the convex NLP 80 in the new partitions to obtain OLB_{j1} and OLB_{j2}. Delete partition if no feasible solution.
4) *Update:* Obtain upper bounds, OUB_{j1} and OUB_{j2} to new partitions if present. Set $k=k+1$, update partition sets and go to step 1.

Example: To illustrate the spatial branch-and-bound algorithm, consider the global solution of:

$$\begin{aligned}&\mathrm{Min}\ f(x)=5/2\,x^4-20\,x^3+55\,x_2-57\,x\\ &\text{s.t. } 0.5\leq x\leq 2.5\end{aligned} \tag{89}$$

Figure 43. Global optimization example with partitions

As seen in Figure 43, this problem has local solutions at $x^* = 2.5$ and at $x^* = 0.8749$. The latter is also the global solution with $f(x^*) = -19.7$. To find the global solution we note that all but the $-20\ x^3$ term in problem 89 are convex, so we replace this term by a new variable and a linear underestimator within a particular subregion, i.e.:

$$\begin{aligned} \text{Min} \quad & f_L\,(x) = 5/2\,x^4 - 20\,w + 55\,x_2 - 57\,x \\ \text{s.t.} \quad & x_1 \le x \le x_u \\ & w = (x_l)^3\,\frac{(x_u - x)}{(x_u - x_l)} + (x_u)^3\,\frac{(x - x_l)}{(x_u - x_l)} \end{aligned} \tag{90}$$

In Figure 43 we also propose subregions that are created by simple bisection partitioning rules, and we use a "loose" bounding tolerance of $\varepsilon = 0.2$. In each partition the lower bound, f_{L} is determined by problem 90 and the upper bound f_{U} is determined by the local solution of the original problem in the subregion. Figure 44 shows the progress of the spatial branch-and-bound algorithm as the partitions are refined and the bounds are updated. In Figure 43, note the definitions of the partitions for the nodes, and the sequence numbers in each node that show the order in which the partitions are processed. The grayed partitions correspond to the deleted subregions and at termination of the algorithm we see that $f_{\mathrm{L}j} \ge f_{\mathrm{U}} - \varepsilon$ (i.e., $-19.85 \ge -19.7 - 0.2$), with the gray subregions in Figure 43 still active. Further partitioning in these subregions will allow the lower and upper bounds to converge to a tighter tolerance.

A number of improvements can be made to the bounding, refinement, and selection strategies in the algorithm that accelerate the convergence of this method. A comprehensive discussion of all of these options can be found in [222 – 224]. Also, a number of efficient global optimization codes have recently been developed, including αBB, BARON, LGO, and OQNLP. An interesting numerical comparison of these and other codes can be found in [225].

10.5. Mixed Integer Programming

Mixed integer programming deals with both discrete and continuous decision variables. For simplicity in the presentation we consider the most common case where the discrete decisions are binary variables, i.e., $y_i = 0$ or 1, and we consider the mixed integer problem 51. Unlike local optimization methods, there are no optimality conditions, like the KKT conditions, that can be applied directly.

Mixed Integer Linear Programming. If the objective and constraint functions are all linear in problem 51, and we assume 0–1 binary variables for the discrete variables, then this gives rise to a mixed integer linear programming (MILP) problem given by Equation 91.

$$\begin{aligned} \text{Min} \quad & Z = a^T x + c^T y \\ \text{s.t.} \quad & Ax + By \le b \\ & x \ge 0,\ y \in \{0,1\}^t \end{aligned} \tag{91}$$

As is well known, the (MILP) problem is NP-hard. Nevertheless, an interesting theoretical result is that it is possible to transform it into an LP with the convexification procedures proposed by Lovacz and Schrijver [226], Sherali and Adams [227], and Balas et al. [228]. These procedures consist of sequentially lifting the original relaxed $x - y$ space into higher dimension and projecting it back to the original space so as to yield, after a finite number of steps, the integer convex hull. Since the transformations have exponential complexity, they are only of theoretical interest, although they can be used as a basis for deriving cutting planes (e.g. lift and project method by [228]).

As for the solution of problem (MILP), it should be noted that this problem becomes an LP problem when the binary variables are relaxed as continuous variables $0 \le y \le 1$. The most common solution algorithms for problem

Figure 44. Spatial branch-and-bound sequence for global optimization example

(MILP) are LP-based branch-and-bound methods, which are enumeration methods that solve LP subproblems at each node of the search tree. This technique was initially conceived by LAND and DOIG [229], BALAS [230], and later formalized by DAKIN, [231]. Cutting-plane techniques, which were initially proposed by GOMORY [232], and consist of successively generating valid inequalities that are added to the relaxed LP, have received renewed interest through the works of CROWDER et al. [233], VAN ROY and WOLSEY [234], and especially the lift-and-project method of BALAS et al. [228]. A recent review of branch-and-cut methods can be found in [235]. Finally, Benders decomposition [236] is another technique for solving MILPs in which the problem is successively decomposed into LP subproblems for fixed 0–1 and a master problem for updating the binary variables.

LP-Based Branch and Bound Method. We briefly outline in this section the basic ideas behind the branch-and-bound method for solving MILP problems. Note that if we relax the t binary variables by the inequalities $0 \leq y \leq 1$ then 91 becomes a linear program with a (global) solution that is a lower bound to the MILP 91. There are specific MILP classes in which the LP relaxation of 91 has the same solution as the MILP. Among these problems is the well-known *assignment problem*. Other MILPs that can be solved with efficient special-purpose methods are the *knapsack* problem, the *set-covering* and *set-partitioning* problems, and the *traveling salesman* problem. See [237] for a detailed treatment of these problems.

The branch-and-bound algorithm for solving MILP problems [231] is similar to the spatial branch-and-bound method of the previous section that explores the search space. As seen in Figure 45, binary variables are successively fixed to define the search tree and a number of bounding properties are exploited in order to fathom nodes in to avoid exhaustive enumeration of all the nodes in the tree.

Figure 45. Branch and bound sequence for MILP example

The basic idea in the search is as follows. The top, or root node, in the tree is the solution to the linear programming relaxation of 91. If all the

y variables take on 0–1 values, the MILP problem is solved, and no further search is required. If at least one of the binary variables yields a fractional value, the solution of the LP relaxation yields a lower bound to problem 91. The search then consists of branching on that node by fixing a particular binary variable to 0 or 1, and the corresponding restricted LP relaxations are solved that in turn yield a lower bound for any of their descendant nodes. In particular, the following properties are exploited in the branch-and-bound search:

- Any node (initial, intermediate, leaf node) that leads to feasible LP solution corresponds to a valid upper bound to the solution of the MILP problem 91.
- Any intermediate node with an infeasible LP solution has infeasible leaf nodes and can be fathomed (i.e., all remaining children of this node can be eliminated).
- If the LP solution at an intermediate node is not less than an existing integer solution, then the node can be fathomed.

These properties lead to pruning of the nodes in the search tree. Branching then continues in the tree until the upper and lower bounds converge.

The basic concepts outlined above lead to a branch-and-bound algorithm with the following features. LP solutions at intermediate nodes are relatively easy to calculate since they can be effectively updated with the dual simplex method. The selection of binary variables for branching, known as the *branching rule,* is based on a number of different possible criteria; for instance, choosing the fractional variable closest to 0.5, or the one involving the largest of the smallest pseudocosts for each fractional variable. *Branching strategies* to navigate the tree take a number of forms. More common *depth-first strategies* expand the most recent node to a leaf node or infeasible node and then backtrack to other branches in the tree. These strategies are simple to program and require little storage of past nodes. On the other hand, *breadth-first strategies* expand all the nodes at each level of the tree, select the node with the lowest objective function, and then proceed until the leaf nodes are reached. Here, more storage is required, but generally fewer nodes are evaluated than in depth-first search. In practice, a combination of both strategies is commonly used: branch on the dichotomy 0–1 at each node (i.e., like breadth-first), but expand as in depth-first. Additional description of these strategies can be found in [237].

Example: To illustrate the branch-and-bound approach, we consider the MILP:

$$\begin{aligned} \text{Min} \quad & Z = x + y_1 + 2y_2 + 3y_3 \\ \text{s.t.} \quad & -x + 3y_1 + y_2 + 2y_3 \le 0 \\ & -4y_1 - 8y_2 - 3y_3 \le -10 \\ & x \ge 0, y_1, y_2, y_3 = \{0,1\} \end{aligned} \tag{92}$$

The solution to problem 92 is given by $x = 4$, $y_1 = 1$, $y_2 = 1$, $y_3 = 0$, and $Z = 7$. Here we use a depth-first strategy and branch on the variables closest to zero or one. Figure 45 shows the progress of the branch-and-bound algorithm as the binary variables are selected and the bounds are updated. The sequence numbers for each node in Figure 45 show the order in which they are processed. The grayed partitions correspond to the deleted nodes and at termination of the algorithm we see that $Z = 7$ and an integer solution is obtained at an intermediate node where coincidentally $y_3 = 0$.

Mixed integer linear programming (MILP) methods and codes have been available and applied to many practical problems for more than twenty years (e.g., [237]. The LP-based branch-and-bound method [231] has been implemented in powerful codes such as OSL, CPLEX, and XPRESS. Recent trends in MILP include the development of branch-and-price [238] and branch-and-cut methods such as the lift-and-project method [228] in which cutting planes are generated as part of the branch-and-bound enumeration. See also [235] for a recent review on MILP. A description of several MILP solvers can also be found in the NEOS Software Guide.

Mixed Integer Nonlinear Programming The most basic form of an MINLP problem when represented in algebraic form is as follows:

$$\begin{aligned} & \min z = f(x,y) \\ & s.t.\ g_j(x,y) \le 0 \quad j \in J \qquad \text{(P1)} \\ & x \in X,\ y \in Y \end{aligned} \tag{93}$$

where $f(\cdot)$, $g(\cdot)$ are *convex, differentiable* functions, J is the index set of inequalities, and x and y are the continuous and discrete

variables, respectively. The set X is commonly assumed to be a convex compact set, e.g., $X=\{x|x\in\mathbf{R}^n, Dx\leq d, x^L\leq x\leq x^U\}$; the discrete set Y corresponds to a polyhedral set of integer points, $Y=\{y|x\in Z^m, Ay\leq a\}$, which in most applications is restricted to 0–1 values, $y\in\{0,1\}^m$. In most applications of interest the objective and constraint functions $f(\cdot)$, $g(\cdot)$ are linear in y (e.g., fixed cost charges and mixed-logic constraints): $f(x,y)=c^T y+r(x)$, $g(x,y)=By+h(x)$.

Methods that have addressed the solution of problem 93 include the branch-and-bound method (BB) [239 – 243], generalized Benders decomposition (GBD) [244], outer-approximation (OA) [245 – 247], LP/NLP based branch-and-bound [248], and extended cutting plane method (ECP) [249].

There are three basic *NLP subproblems* that can be considered for problem 93:

a) NLP relaxation

$$\begin{aligned} &\text{Min } Z_{LB}^k = f(x,y) \\ &s.t.\ g_j(x.y)\leq 0\ j\in J \\ &\quad x\in X, y\in Y_R \qquad \text{(NLP1)} \\ &\quad y_i\leq\alpha_i^k\ i\in I_{FL}^k \\ &\quad y_i\geq\beta_i^k\ i\in I_{FU}^k \end{aligned} \tag{94}$$

where Y_{R} is the continuous relaxation of the set Y, and $I_{\mathrm{FL}}^k, I_{\mathrm{FU}}^k$ are index subsets of the integer variables y_i, $i\in I$ which are restricted to lower and upper bounds α_i^k, β_i^k at the k-th step of a branch-and-bound enumeration procedure. Note that $\alpha_i^k=\lfloor y_i^l\rfloor, \beta_i^k=\lceil y_i^m\rceil, l<k, m<k$, where y_i^l, y_i^m are noninteger values at a previous step, and $\lfloor\cdot\rfloor$, $\lceil\cdot\rceil$ are the floor and ceiling functions, respectively.

Also note that if $I_{\mathrm{FU}}^k=I_{\mathrm{FL}}^k=\varnothing\ (k=0)$, problem 94 corresponds to the continuous NLP relaxation of problem 93. Except for few and special cases, the solution to this problem yields in general a noninteger vector for the discrete variables. Problem 94 also corresponds to the k-th step in a branch-and-bound search. The optimal objective function $Z_{\mathrm{LB}}^{\mathrm{o}}$ provides an absolute lower bound to problem 93; for $m\geq k$, the bound is only valid for $I_{\mathrm{FL}}^k\subset I_{\mathrm{FL}}^m$, $I_{\mathrm{FU}}^k\subset I_{\mathrm{FL}}^m$.

b) NLP subproblem for fixed y^k:

$$\begin{aligned} &\text{Min}\quad Z_{\mathrm{U}}^k = f(x,y^k) \\ &\text{s.t.}\quad g_j(x,y^k)\leq 0\quad j\in J \\ &\qquad x\in X \end{aligned} \tag{95}$$

which yields an upper bound Z_{U}^k to problem 93 provided problem 95 has a feasible solution. When this is not the case, we consider the next subproblem:

c) Feasibility subproblem for fixed y^{k}:

$$\begin{aligned} &\text{Min } u \\ &\text{s.t. } g_j(x,y^k)\leq u\ j\in J \\ &\quad x\in X, u\in R^1 \end{aligned} \tag{96}$$

which can be interpreted as the minimization of the infinity-norm measure of infeasibility of the corresponding NLP subproblem. Note that for an infeasible subproblem the solution of problem 96 yields a strictly positive value of the scalar variable u.

Figure 46. Geometrical interpretation of linearizations in master problem 97

The convexity of the nonlinear functions is exploited by replacing them with supporting hyperplanes, which are generally, but not necessarily, derived at the solution of the NLP subproblems. In particular, the new values y^K (or (x^K, y^K) are obtained from a *cutting-plane MILP problem* that is based on the K points (x^k, y^k), $k = 1 \ldots K$, generated at the K previous steps:

$$\begin{array}{l} \text{Min } Z_{\mathrm{L}}^K = \alpha \\ \text{st} \quad \left.\begin{array}{l} \alpha \geq f(x^k, y^k) \\ \quad + \nabla f(x^k, y^k)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \\ g_j(x^k, y^k) \\ \quad + \nabla g_j(x^k, y^k)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \leq 0 \; j \in J^k \end{array}\right\} k = 1, \ldots K \\ \qquad x \in X, \; y \in Y \end{array} \tag{97}$$

where $J^k \supseteq J$. When only a subset of linearizations is included, these commonly correspond to violated constraints in problem 93. Alternatively, it is possible to include all linearizations in problem 97. The solution of 97 yields a valid lower bound Z_{L}^k to problem 93. This bound is nondecreasing with the number of linearization points K. Note that since the functions $f(x,y)$ and $g(x,y)$ are convex, the linearizations in problem 97 correspond to outer approximations of the nonlinear feasible region in problem 93. A geometrical interpretation is shown in Figure 46, where it can be seen that the convex objective function is being underestimated, and the convex feasible region overestimated with these linearizations.

Algorithms. The different methods can be classified according to their use of the subproblems 94–96, and the specific specialization of the MILP problem 97, as seen in Figure 47. In the GBD and OA methods (case b), as well in the LP/NLP-based branch-and-bound mehod (case d), problem 96 is solved if infeasible subproblems are found. Each of the methods is explained next in terms of the basic subproblems.

Branch and Bound. While the earlier work in branch and bound (BB) was aimed at linear problems [231] this method can also be applied to nonlinear problems [239 – 243]. The BB method starts by solving first the continuous NLP relaxation. If all discrete variables take integer values the search is stopped. Otherwise, a tree search is performed in the space of the integer variables y_i, $i \in I$. These are successively fixed at the corresponding nodes of the tree, giving rise to relaxed NLP subproblems of the form (NLP1) which yield lower bounds for the subproblems in the descendant nodes. Fathoming of nodes occurs when the lower bound exceeds the current upper bound, when the subproblem is infeasible, or when all integer variables y_i take on discrete values. The last-named condition yields an upper bound to the original problem.

Figure 47. Major steps in the different algorithms

The BB method is generally only attractive if the NLP subproblems are relatively inexpensive to solve, or when only few of them need to be solved. This could be either because of the low dimensionality of the discrete variables, or because the integrality gap of the continuous NLP relaxation of 93 is small.

Outer Approximation [245 – 247]**.** The OA method arises when NLP subproblems 95 and MILP master problems 97 with $J^k = J$ are solved successively in a cycle of iterations to generate the points (x^k, y^k). Since the master problem 97 requires the solution of all feasible discrete variables y^k, the following MILP

relaxation is considered, assuming that the solution of K different NLP subproblems ($K = |\mathrm{KFS} \cup \mathrm{KIS}|$), where KFS is a set of solutions from problem 95, and KIS set of solutions from problem 96 is available:

$$\begin{aligned} &\text{Min } Z_{\mathrm{L}}^{K} = \alpha \\ &\text{st} \quad \left.\begin{aligned} &\alpha \geq f(x^k, y^k) \\ &\quad + \nabla f(x^k, y^k)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \\ &g_j(x^k, y^k) \\ &\quad + \nabla g_j(x^k, y^k)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \leq 0 \quad j \in J \end{aligned}\right\} k = 1, \ldots K \\ &\qquad x \in X, y \in Y \end{aligned} \tag{98}$$

Given the assumption on convexity of the functions $f(x,y)$ and $g(x,y)$, it can be proved that the solution of problem 98 Z_{L}^{k} corresponds to a lower bound of the solution of problem 93. Note that this property can be verified in Figure 46. Also, since function linearizations are accumulated as iterations proceed, the master problems 98 yield a nondecreasing sequence of lower bounds $Z_{\mathrm{L}}^{1} \ldots \leq Z_{\mathrm{L}}^{k} \ldots Z_{\mathrm{L}}^{k}$ since linearizations are accumulated as iterations k proceed.

The OA algorithm as proposed by Duran and Grossmann consists of performing a cycle of major iterations, $k = 1,..K$, in which problem 95 is solved for the corresponding y^K, and the relaxed MILP master problem 98 is updated and solved with the corresponding function linearizations at the point (x^k, y^k) for which the corresponding subproblem NLP2 is solved. If feasible, the solution to that problem is used to construct the first MILP master problem; otherwise a feasibility problem 96 is solved to generate the corresponding continuous point [247]. The initial MILP master problem 98 then generates a new vector of discrete variables. The subproblems 95 yield an upper bound that is used to define the best current solution, $\mathrm{UB}^k = \min_k \left\{ Z_{\mathrm{U}}^{k} \right\}$. The cycle of iterations is continued until this upper bound and the lower bound of the relaxed master problem Z_{L}^{k} are within a specified tolerance. One way to avoid solving the feasibility problem 96 in the OA algorithm when the discrete variables in problem 93 are 0–1, is to introduce the following integer cut whose objective is to make infeasible the choice of the previous 0–1 values generated at the K previous iterations [245]:

$$\sum_{i \in B^k} y_i - \sum_{i \in N^k} y_i \leq \left| B^k \right| - 1 \quad k = 1, \ldots K \tag{99}$$

where $B^k = \left\{ i | y_i^k = 1 \right\}$, $N^k = \left\{ i | y_i^k = 0 \right\}$, $k = 1, \ldots K$. This cut becomes very weak as the dimensionality of the 0–1 variables increases. However, it has the useful feature of ensuring that new 0–1 values are generated at each major iteration. In this way the algorithm will not return to a previous integer point when convergence is achieved. Using the above integer cut the termination takes place as soon as $Z_{\mathrm{L}}^{K} \geq \mathrm{UB}^K$.

The OA algorithm trivially converges in one iteration if $f(x,y)$ and $g(x,y)$ are linear. This property simply follows from the fact that if $f(x,y)$ and $g(x,y)$ are linear in x and y the MILP master problem 98 is identical to the original problem 93. It is also important to note that the MILP master problem need not be solved to optimality.

Generalized Benders Decomposition (GBD) [244]**.** The GBD method [250] is similar to the outer-approximation method. The difference arises in the definition of the MILP master problem 97. In the GBD method only active inequalities are considered $J^k = \{ j | \, g_j(x^k, y^k) = 0 \}$ and the set $x \in X$ is disregarded. In particular, consider an outer-approximation given at a given point (x^k, y^k)

$$\begin{aligned} &\alpha \geq f\left(x^k, y^k\right) + \nabla f\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \\ &g\left(x^k, y^k\right) + \nabla g\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \leq 0 \end{aligned} \tag{100}$$

where for a fixed y^k the point x^k corresponds to the optimal solution to problem 95. Making use of the Karush – Kuhn – Tucker conditions and eliminating the continuous variables x, the inequalities in 100 can be reduced as follows [248]:

$$\begin{aligned} &\alpha \geq f\left(x^k, y^k\right) + \nabla_y f\left(x^k, y^k\right)^T \left(y - y^k\right) + \\ &\left(\mu^k\right)^T \left[g\left(x^k, y^k\right) + \nabla_y g\left(x^k, y^k\right)^T \left(y - y^k\right) \right] \end{aligned} \tag{101}$$

which is the Lagrangian cut projected in the y-space. This can be interpreted as a surrogate constraint of the equations in 100, because it is obtained as a linear combination of these.

For the case when there is no feasible solution to problem 95, then if the point x^k is obtained from the feasibility subproblem (NLPF), the following feasibility cut projected in y can be obtained using a similar procedure.

$$\left(\lambda^k\right)^T \left[g\left(x^k,y^k\right)+\nabla_y g\left(x^k,y^k\right)^T\left(y-y^k\right)\right] \leq 0 \tag{102}$$

In this way, problem 97 reduces to a problem projected in the y-space:

$$\begin{aligned}
&\text{Min} \quad Z_{\mathrm{L}}^K=\alpha \\
&\text{st}\ \alpha \geq \quad f\left(x^k,y^k\right)+\nabla_y f\left(x^k,y^k\right)^T\left(y-y^k\right)+ \\
&\left(\mu^k\right)^T\left[g\left(x^k,y^k\right)+\nabla_y g\left(x^k,y^k\right)^T\left(y-y^k\right)\right] \\
&\qquad k\in KFS \\
&\left(\lambda^k\right)^T\left[g\left(x^k,y^k\right)+\nabla_y g\left(x^k,y^k\right)^T\left(y-y^k\right)\right] \leq 0 \\
&\qquad k\in KIS \\
&x\in X, \alpha\in R^1
\end{aligned}$$

where KFS is the set of feasible subproblems 95, and KIS the set of infeasible subproblems whose solution is given by problem 96. Also $|\mathrm{KFS} \cup \mathrm{KIS}| = K$. Since master problem 103 can be derived from master problem 98, in the context of problem 93, GBD can be regarded as a particular case of the outer-approximation algorithm. In fact one can prove that given the same set of K subproblems, the lower bound predicted by the relaxed master problem 98 is greater than or equal to that predicted by the relaxed master problem 103 [245]. This proof follows from the fact that the Lagrangian and feasibility cuts 101 and 102 are surrogates of the outer-approximations 100. Given the fact that the lower bounds of GBD are generally weaker, this method commonly requires a larger number of cycles or major iterations. As the number of 0–1 variables increases this difference becomes more pronounced. This is to be expected since only one new cut is generated per iteration. Therefore, user-supplied constraints must often be added to the master problem to strengthen the bounds. Also, it is sometimes possible to generate multiple cuts from the solution of an NLP subproblem in order to strengthen the lower bound [251]. As for the OA algorithm, the trade-off is that while it generally predicts stronger lower bounds than GBD, the computational cost for solving the master problem (M-OA) is greater, since the number of constraints added per iteration is equal to the number of nonlinear constraints plus the nonlinear objective.

If problem 93 has zero integrality gap, the GBD algorithm converges in one iteration once the optimal (x^*, y^*) is found [252]. This property implies that the only case in which one can expect the GBD method to terminate in one iteration is that in which the initial discrete vector is the optimum, and when the objective value of the NLP relaxation of problem 93 is the same as the objective of the optimal mixed-integer solution.

Extended Cutting Plane (ECP) [249]**.** The ECP method, which is an extension of Kelley's cutting-plane algorithm for convex NLP [253], does not rely on the use of NLP subproblems and algorithms. It relies only on the iterative solution of problem 97 by successively adding a linearization of the most violated constraint at the predicted point (x^k, y^k):

$$J^k=\{\hat{j}\in\arg\left\{\max_{j\in J} g_j\left(x^k,y^k\right)\right\}\}$$

Convergence is achieved when the maximum constraint violation lies within the specified tolerance. The optimal objective value of problem 97 yields a nondecreasing sequence of lower bounds. It is of course also possible to either add to problem 97 linearizatons of all the violated constraints in the set J^k, or linearizations of all the nonlinear constraints $j \in J$. In the ECP method the objective must be defined as a linear function, which can easily be accomplished by introducing a new variable to transfer nonlinearities in the objective as an inequality.

Note that since the discrete and continuous variables are converged simultaneously, the ECP method may require a large number of iterations. However, this method shares with the OA method Property 2 for the limiting case when all the functions are linear.

LP/NLP-Based Branch and Bound [248]**.** This method is similar in spirit to a branch-and-cut method, and avoids the complete solution of the MILP master problem (M-OA) at each major iteration. The method starts by solving an initial NLP subproblem, which is linearized as in (M-OA). The basic idea consists then of performing an LP-based branch-and-bound method for (M-OA) in which NLP subproblems 95 are solved at those nodes in which feasible integer solutions

are found. By updating the representation of the master problem in the current open nodes of the tree with the addition of the corresponding linearizations, the need to restart the tree search is avoided.

This method can also be applied to the GBD and ECP methods. The LP/NLP method commonly reduces quite significantly the number of nodes to be enumerated. The trade-off, however, is that the number of NLP subproblems may increase. Computational experience has indicated that often the number of NLP subproblems remains unchanged. Therefore, this method is better suited for problems in which the bottleneck corresponds to the solution of the MILP master problem. Leyffer [254] has reported substantial savings with this method.

Example: Consider the following MINLP problem, whose objective function and constraints contain nonlinear convex terms

$$\begin{aligned} &\text{Min } Z = y_1 + 1.5y_2 + 0.5y_3 + x_1^2 + x_2^2 \\ &s.t. \quad (x_1-2)^2 - x_2 \le 0 \\ &\qquad x_1 - 2y_1 \ge 0 \\ &\qquad x_1 - x_2 - 4(1-y_2) \ge 0 \\ &\qquad x_2 - y_2 \ge 0 \\ &\qquad x_1 + x_2 \ge 3y_3 \\ &\qquad y_1 + y_2 + y_3 \ge 1 \\ &\qquad 0 \le x_1 \le 4, 0 \le x_2 \le 4 \\ &\qquad y_1, y_2, y_3 = 0,1 \end{aligned} \tag{103}$$

The optimal solution of this problem is given by $y_1 = 0$, $y_2 = 1$, $y_3 = 0$, $x_1 = 1$, $x_2 = 1$, $Z = 3.5$. Figure 48 shows the progress of the iterations with the OA and GBD methods, while the table lists the number of NLP and MILP subproblems that are solved with each of the methods. For the case of the MILP problems the total number of LPs solved at the branch-and-bound nodes are also reported.

Extensions of MINLP Methods. Extensions of the methods described above include a quadratic approximation to (RM-OAF) [247] using an approximation of the Hessian matrix. The quadratic approximations can help to reduce the number of major iterations, since an improved representation of the continuous space is obtained. This, however, comes at the price of having to solve an MIQP instead of an MILP at each iteration.

Figure 48. Progress of iterations with OA and GBD methods, and number of subproblems for the BB, OA, GBD, and ECP methods.

The master problem 98 can involve a rather large number of constraints, due to the accumulation of linearizations. One option is to keep only the last linearization point, but this can lead to nonconvergence even in convex problems, since then the monotonic increase of the lower bound is not guaranteed. As shown [248], linear approximations to the nonlinear objective and constraints can be aggregated with an MILP master problem that is a hybrid of the GBD and OA methods.

For the case when linear equalities of the form $h(x, y) = 0$ are added to problem 93 there is no major difficulty, since these are invariant to the linearization points. If the equations are nonlinear, however, there are two difficulties. First, it is not possible to enforce the linearized equalities at K points. Second, the nonlinear equations may generally introduce nonconvexities, unless they relax as convex inequalities [255]. Kocis and Grossmann [256] proposed an equality relaxation strategy in which the nonlinear equalities are replaced by the inequalities

$$T^k \nabla h\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \le 0 \tag{104}$$

where $T^k = \{t_{ii}^k\}$, and $t_{ii}^k = \text{sign}\left(\lambda_i^k\right)$ sign in which λ_i^k is the multiplier associated to the equation $h_i(x, y) = 0$. Note that if these equations relax as the inequalities $h(x, y) \leq 0$ for all y and $h(x, y)$ is convex, this is a rigorous procedure. Otherwise, nonvalid supports may be generated. Also, in the master problem 103 of GBD, no special provision is required to handle equations, since these are simply included in the Lagrangian cuts. However, similar difficulties as in OA arise if the equations do not relax as convex inequalities.

When $f(x,y)$ and $g(x,y)$ are nonconvex in problem 93, or when nonlinear equalities $h(x, y) = 0$ are present, two difficulties arise. First, the NLP subproblems 94 – 96 may not have a unique local optimum solution. Second, the master problem (M-MIP) and its variants (e.g., M-MIPF, M-GBD, M-MIQP) do not guarantee a valid lower bound Z_{L}^K or a valid bounding representation with which the global optimum may be cut off.

Rigorous global optimization approaches for addressing nonconvexities in MINLP problems can be developed when special structures are assumed in the continuous terms (e.g. bilinear, linear fractional, concave separable). Specifically, the idea is to use convex envelopes or underestimators to formulate lower-bounding convex MINLP problems. These are then combined with global optimization techniques for continuous variables [206, 207, 209, 214, 216, 222, 257], which usually take the form of spatial branch-and-bound methods. The lower bounding MINLP problem has the general form,

$$\begin{aligned} &\text{Min } Z = \overline{f}\,(x,y) \\ &\text{s.t. } \overline{g}_j\,(x,y) \leq 0 \; j \in J \\ &\quad x \in X,\, y \in Y \end{aligned} \tag{105}$$

where $\overline{f}, \overline{g}$ are valid convex underestimators such that $\overline{f}\,(x,y) \leq f\,(x,y)$ and the inequalities $\overline{g}\,(x,y) \leq 0$ are satisfied if $g\,(x,y) \leq 0$. A typical example of convex underestimators are the convex envelopes for bilinear terms [208].

Examples of global optimization methods for MINLP problems include the branch-and-reduce method [209, 210], the α-BB method [212], the reformulation/spatial branch-and-bound search method [258], the branch-and-cut method [259], and the disjunctive branch-and-bound method [260]. All these methods rely on a branch-and-bound procedure. The difference lies in how to perform the branching on the discrete and continuous variables. Some methods perform the spatial tree enumeration on both the discrete and continuous variables of problem 105. Other methods perform a spatial branch and bound on the continuous variables and solve the corresponding MINLP problem 105 at each node using any of the methods reviewed above. Finally, other methods branch on the discrete variables of problem 105, and switch to a spatial branch and bound on nodes where a feasible value for the discrete variables is found. The methods also rely on procedures for tightening the lower and upper bounds of the variables, since these have a great effect on the quality of the underestimators. Since the tree searches are not finite (except for ε convergence), these methods can be computationally expensive. However, their major advantage is that they can rigorously find the global optimum. Specific cases of nonconvex MINLP problems have been handled. An example is the work of Pörn and Westerlund [261], who addressed the solution of MINLP problems with pseudoconvex objective function and convex inequalities through an extension of the ECP method.

The other option for handling nonconvexities is to apply a heuristic strategy to try to reduce as much as possible the effect of nonconvexities. While not being rigorous, this requires much less computational effort. We describe here an approach for reducing the effect of nonconvexities at the level of the MILP master problem.

Viswanathan and Grossmann [262] proposed to introduce slacks in the MILP master problem to reduce the likelihood of cutting off feasible solutions. This master problem (augmented penalty/equality relaxation) has the form:

$$\begin{aligned} &\min Z^K = \alpha + \sum_{k=1}^{K} w_p^k\, p^k + w_q^k\, q^k \\ &\left.\begin{aligned} \text{s.t.}\quad & \alpha \geq f\left(x^k, y^k\right) \\ & \quad + \nabla f\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \\ & T^k \nabla h\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \leq p^k \\ & g\left(x^k, y^k\right) + \nabla g\left(x^k, y^k\right)^T \begin{bmatrix} x - x^k \\ y - y^k \end{bmatrix} \\ & \quad \leq q^k \end{aligned}\right\} k = 1, \ldots K \end{aligned} \tag{106}$$

$$\sum_{i\in B^k} y_i - \sum_{i\in N^k} y_i \leq \left|B^k\right| - 1 \; k=1,\ldots K$$
$$x\in X, y\in Y, \alpha\in R^1, p^k, q^k \geq 0$$

where w_p^k, w_q^k are weights that are chosen sufficiently large (e.g., 1000 times the magnitude of the Lagrange multiplier). Note that if the functions are convex then the MILP master problem 106 predicts rigorous lower bounds to problem 93 since all the slacks are set to zero.

Computer Codes for MINLP. Computer codes for solving MINLP problems include the following. The program DICOPT [262] is an MINLP solver that is available in the modeling system GAMS [263]. The code is based on the master problem 106 and the NLP subproblems 95. This code also uses relaxed 94 to generate the first linearization for the above master problem, with which the user need not specify an initial integer value. Also, since bounding properties of problem 106 cannot be guaranteed, the search for nonconvex problems is terminated when there is no further improvement in the feasible NLP subproblems. This is a heuristic that works reasonably well in many problems. Codes that implement the branch-and-bound method using subproblems 94 include the code MINLP_BB, which is based on an SQP algorithm [243] and is available in AMPL, the code BARON [264], which also implements global optimization capabilities, and the code SBB, which is available in GAMS [263]. The code a-ECP implements the extended cutting-plane method [249], including the extension by Pörn and Westerlund [261]. Finally, the code MINOPT [265] also implements the OA and GBD methods, and applies them to mixed-integer dynamic optimization problems. It is difficult to derive general conclusions on the efficiency and reliability of all these codes and their corresponding methods, since no systematic comparison has been made. However, one might anticipate that branch-and-bound codes are likely to perform better if the relaxation of the MINLP is tight. Decomposition methods based on OA are likely to perform better if the NLP subproblems are relatively expensive to solve, while GBD can perform with some efficiency if the MINLP is tight and there are many discrete variables. ECP methods tend to perform well on mostly linear problems.

Logic-Based Optimization. Given difficulties in the modeling and solution of mixed integer problems, the following major approaches based on logic-based techniques have emerged: generalized disjunctive programming 107 [266], mixed-logic linear programming (MLLP) [267], and constraint programming (CP) [268]. The motivations for this logic-based modeling has been to facilitate the modeling, reduce the combinatorial search effort, and improve the handling of nonlinearities. In this section we mostly concentrate on generalized disjunctive programming and provide a brief reference to constraint programming. A general review of logic-based optimization can be found in [269, 309].

Generalized disjunctive programming in 107 [266] is an extension of disjunctive programming [270] that provides an alternative way of modeling MILP and MINLP problems. The general formulation 107 is as follows:

$$\begin{aligned}
&\text{Min } Z = \sum_{k\in K} c_k + f(x) \\
&s.t. \quad g(x) \leq 0 \\
&\bigvee_{j\in J_k} \begin{bmatrix} Y_{jk} \\ h_{jk}(x) \leq 0 \\ c_k = \gamma_{jk} \end{bmatrix}, k\in K \\
&\Omega(Y) = True \\
&x\in R^n, c\in R^m, Y\in\{true,\ false\}^m
\end{aligned} \tag{107}$$

where Y_{jk} are the Boolean variables that decide whether a term j in a disjunction $k \in K$ is true or false, and x are continuous variables. The objective function involves the term $f(x)$ for the continuous variables and the charges c_k that depend on the discrete choices in each disjunction $k \in K$. The constraints $g(x) \leq 0$ hold regardless of the discrete choice, and $h_{jk}(x) \leq 0$ are conditional constraints that hold when Y_{jk} is true in the j-th term of the k-th disjunction. The cost variables c_k correspond to the fixed charges, and are equal to γ_{jk} if the Boolean variable Y_{jk} is true. $\Omega(Y)$ are logical relations for the Boolean variables expressed as propositional logic.

Problem 107 can be reformulated as an MINLP problem by replacing the Boolean variables by binary variables y_{jk},

$$\begin{aligned}
&\text{Min } Z=\sum_{k\in K}\sum_{j\in J_k}\gamma_{jk}y_{jk}+f(x)\\
&\text{s.t.}\quad g(x)\le 0\\
&h_{jk}(x)\le M_{jk}\left(1-y_{jk}\right),\ j\in J_k,\ k\in K \qquad \text{(BM)}\\
&\sum_{j\in J_k}y_{jk}=1,\ k\in K\\
&Ay\le a\\
&0\le x\le x^U,\ y_{jk}\in\{0,1\},\ j\in J_k,\ k\in K
\end{aligned} \tag{108}$$

where the disjunctions are replaced by "Big-M" constraints which involve a parameter M_{jk} and binary variables y_{jk}. The propositional logic statements $\Omega(Y)=$ True are replaced by the linear constraints $Ay\le a$ [271] and [272]. Here we assume that x is a nonnegative variable with finite upper bound x^{U}. An important issue in model 108 is how to specify a valid value for the Big-M parameter M_{jk}. If the value is too small, then feasible points may be cut off. If M_{jk} is too large, then the continuous relaxation might be too loose and yield poor lower bounds. Therefore, finding the smallest valid value for M_{jk} is desired. For linear constraints, one can use the upper and lower bound of the variable x to calculate the maximum value of each constraint, which then can be used to calculate a valid value of M_{jk}. For nonlinear constraints one can in principle maximize each constraint over the feasible region, which is a nontrivial calculation.

Lee and Grossmann [273] have derived the *convex hull relaxation* of problem 107. The basic idea is as follows. Consider a disjunction $k\in K$ that has convex constraints

$$\begin{aligned}
&\bigvee_{j\in J_k}\begin{bmatrix} Y_{jk}\\ h_{jk}(x)\le 0\\ c=\gamma_{jk}\end{bmatrix}\\
&0\le x\le x^U, c\ge 0
\end{aligned} \tag{109}$$

where $h_{jk}(x)$ are assumed to be convex and bounded over x. The convex hull relaxation of disjunction 109 [242] is given as follows:

$$\begin{aligned}
&x=\sum_{j\in J_k}v^{jk},\quad c=\sum_{j\in J}\lambda_{jk}\gamma_{jk}\\
&0\le v^{jk}\le\lambda_{jk}x^{\mathrm{U}}_{jk},\ j\in J_k\\
&\sum_{j\in J_k}\lambda_{jk}=1,\ 0\le\lambda_{jk}\le 1,\ j\in J_k \qquad \text{(CH)}\\
&\lambda_{jk}h_{jk}\left(v^{jk}/\lambda_{jk}\right)\le 0,\ j\in J_k\\
&x,c,v^{jk}\ge 0,\ j\in J_k
\end{aligned} \tag{110}$$

where v^{jk} are disaggregated variables that are assigned to each term of the disjunction $k\in K$, and λ_{jk} are the weight factors that determine the feasibility of the disjunctive term. Note that when λ_{jk} is 1, then the j-th term in the k-th disjunction is enforced and the other terms are ignored. The constraints $\lambda_{jk}h_{jk}\left(v^{jk}/\lambda_{jk}\right)$ are convex if $h_{jk}(x)$ is convex [274, p. 160]. A formal proof can be found in [242]. Note that the convex hull 110 reduces to the result by Balas [275] if the constraints are linear. Based on the convex hull relaxation 110, Lee and Grossmann [273] proposed the following convex relaxation program of problem 107.

$$\begin{aligned}
&\text{Min } Z^L=\sum_{k\in K}\sum_{j\in J_k}\gamma_{jk}\lambda_{jk}+f(x)\\
&\text{s.t.}\quad g(x)\le 0\\
&x=\sum_{j\in J_k}v^{jk},\ \sum_{j\in J_k}\lambda_{jk}=1,\ k\in K \qquad \text{(CRP)}\\
&0\le x,\ v^{jk}\le x^{\mathrm{U}},\ 0\le\lambda_{jk}\le 1,\ j\in J_k,\ k\in K\\
&\lambda_{jk}h_{jk}\left(v^{jk}/\lambda_{jk}\right)\le 0,\ j\in J_k,\ k\in K\\
&A\lambda\le a\\
&0\le x,\ v^{jk}\le x^{\mathrm{U}},\ 0\le\lambda_{jk}\le 1,\ j\in J_k,\ k\in K
\end{aligned} \tag{111}$$

where x^{U} is a valid upper bound for x and v. Note that the number of constraints and variables increases in problem 111 compared with problem 107. Problem 111 has a unique optimal solution and it yields a valid lower bound to the optimal solution of problem 107 [273]. Grossmann and Lee [276] proved that problem 111 has the useful property that the lower bound is greater than or equal to the lower bound predicted from the relaxation of problem 108.

Further description of algorithms for disjunctive programming can be found in [277].

Constraint Programming. Constraint programming (CP) [268, 269] is a relatively new modeling and solution paradigm that was originally developed to solve feasibility problems, but it has been extended to solve optimization problems as well. Constraint programming is very expressive, as continuous, integer, and Boolean variables are permitted and, moreover, variables can be indexed by other variables. Constraints can be expressed in algebraic form (e.g., $h(x)\le 0$), as disjunctions (e.g., $[A_1x\le b_1]\vee A_2x\le b_2]$), or as conditional logic statements (e.g., If $g(x)\le 0$ then $r(x)\le 0$). In addition, the language can support special implicit functions such as the all-different $(x_1, x_2, \ldots x_n)$ constraint for

assigning different values to the integer variables $x_1, x_2, \ldots x_n$. The language consists of C++ procedures, although the recent trend has been to provide higher level languages such as OPL. Other commercial CP software packages include ILOG Solver [278], CHIP [279], and ECLiPSe [280].

10.6. Dynamic Optimization

Interest in dynamic simulation and optimization of chemical processes has increased significantly during the last two decades. Chemical processes are modeled dynamically using differential-algebraic equations (DAEs), consisting of differential equations that describe the dynamic behavior of the system, such as mass and energy balances, and algebraic equations that ensure physical and thermodynamic relations. Typical applications include control and scheduling of batch processes; startup, upset, shut-down, and transient analysis; safety studies; and the evaluation of control schemes. We state a general differential-algebraic optimization problem 112 as follows:

$$\begin{aligned}
&\text{Min} && \Phi\left(z\left(t_{\mathrm{f}}\right); y\left(t_{\mathrm{f}}\right); u\left(t_{\mathrm{f}}\right); t_{\mathrm{f}}; p\right) \\
&\text{s.t.} && F\left(dz/dt; z(t); u(t); t; p\right)=0,\ z(0)=z_0 \\
& && G_{\mathrm{s}}\left[z\left(t_{\mathrm{s}}\right); y\left(t_{\mathrm{s}}\right); u\left(t_{\mathrm{s}}\right); t_{\mathrm{s}}; p\right]=0 \\
& && z^{\mathrm{L}} \le z(t) \le x^{\mathrm{U}} \\
& && y^{\mathrm{L}} \le y(t) \le y^{\mathrm{U}} \\
& && u^{\mathrm{L}} \le u(t) \le y^{\mathrm{U}} \\
& && p^{\mathrm{L}} \le p \le p^{\mathrm{U}} \\
& && t_{\mathrm{f}}^{t} \le t_{\mathrm{f}} \le t_{\mathrm{f}}^{U}
\end{aligned} \tag{112}$$
